ABSTRACT

We present IRAM Plateau de Bure interferometric detections of CO ($J=1\rightarrow0$) emission from a 24$\mu$m-selected sample of star-forming galaxies at $z=0.4$. The galaxies have PAH 7.7$\mu$m-derived star formation rates of SFR$\sim 30–60 M_\odot$ yr\(^{-1}\) and stellar masses $M_* \sim 10^{11} M_\odot$. The CO ($J=1\rightarrow0$) luminosities of the galaxies imply that the disks still contain a large reservoir of molecular gas, contributing $\sim$20% of the baryonic mass, but have star-formation `efficiencies' similar to local quiescent disks and gas-dominated disks at $z \sim 1.5$ - 2. We reveal evidence that the average molecular gas fraction has undergone strong evolution since $z \sim 2$, with $f_{\text{gas}} \propto (1 + z)^{-2 \pm 0.5}$. The evolution of $f_{\text{gas}}$ encodes fundamental information about the relative depletion/replenishment of molecular fuel in galaxies, and is expected to be a strong function of halo mass. We show that the latest predictions for the evolution of the molecular gas fraction in semi-analytic models of galaxy formation within a $\Lambda$CDM Universe are supported by these new observations.

Subject headings: galaxies: evolution — cosmology: observations

1. INTRODUCTION

Molecular hydrogen is arguably the most important component of the interstellar medium (ISM) in high-redshift galaxies, since it is the phase necessary for, and immediately preceding, star formation. However, observing cool ($\lesssim 50$ K) molecular hydrogen is difficult; the molecule has no permanent electric dipole and so one must rely on tracer molecular hydrogen. This is especially true for, and immediately preceding, star formation. However, observing cool ($\lesssim 50$ K) molecular hydrogen is difficult; the molecule has no permanent electric dipole and so one must rely on tracer molecular hydrogen. This is especially true for, and immediately preceding, star formation. However, observing cool ($\lesssim 50$ K) molecular hydrogen is difficult; the molecule has no permanent electric dipole and so one must rely on tracer molecular emission (the most common being ro-vibrational emission from the $^{12}$CO isotopomer [hereafter `CO']).

Unfortunately, uncertainty of the precise calibration of CO luminosity to total gas mass in both low- and high-$z$ galaxies has made interpretation of results challenging: even in the local Universe there is seen to be metallicity and luminosity dependence on the conversion (Boissier et al. 2003; Blitz et al. 2007; Komugi et al. 2010). Furthermore, although the bulk of the molecular gas in star-forming disks is contained in virialised clouds, it is clear that the most luminous galaxies — mostly mergers — have molecular gas distributions and star-formation modes dramatically different to quiescent disks; they require an alternative molecular mass calibration related to the physical conditions of their interstellar media (Solomon et al. 1997). The importance of understanding how the thermodynamic state of the gas affects the calibration also remains controversial (high-$z$ observations typically target $J_{\text{upper}} > 1$, requiring some correction to $J = (1 \rightarrow 0)$ based on the excitation of the gas; although see Ivison et al. 2010; Harris et al. 2010).

The majority of molecular gas studies at high-$z$ have, necessarily, focused on the most active systems (generally sub-millimeter selected galaxies and quasars), and so comparatively little is known about the evolution of the molecular gas properties of the more common, but less active population. Nevertheless, recent studies have started to make progress in expanding the parameter space of CO observations at high-$z$, and several studies have detected CO emission from `normal' disks at $z = 1–2$ (Daddi et al. 2008; 2010; Tacconi et al. 2010). The striking result it that the efficiency of star-formation in these distant galaxies is claimed to be similar to that seen in local `quiescent' disks (Dannerbauer et al. 2009; Daddi et al. 2010), with enhanced SFRs driven simply by larger gas reservoirs, drained by star-formation (and feedback) on Gyr timescales. This hints that a secular mode of star formation might be ubiquitous in L$^*$ disks independent of cosmic epoch (but see the higher-$z$ results of Coppin et al. 2007 and Riechers et al. 2010).

The aim of this Letter is to further expand the parameter space of molecular gas studies in normal galaxies, building on our observations of luminous infrared galaxies (LIRGs) at $z = 0.4$ (Geach et al. 2009, G09). We present new IRAM Plateau de Bure interferometric (PdBI) observations of a sample of 24$\mu$m-selected galaxies in the outskirts of the rich cluster Cl0024+16 at $z = 0.395$. These galaxies bridge the gap between quiescent, local spirals and luminous, high-redshift starbursts and disks. Throughout we adopt a $\Omega_m = 0.3$, $\Omega_{\Lambda} = 0.7$, $H_0 = 70$ km s$^{-1}$ Mpc$^{-1}$ cosmology.

2. OBSERVATIONS AND DATA REDUCTION

Our sample consists of five Spitzer MIPS 24$\mu$m detected LIRG-class galaxies in the outskirts of the rich cluster Cl0024+16 ($z = 0.395$, see Geach et al. 2006). We obtained mid-infrared spectroscopy with Spitzer IRS to confirm the presence of aromatic features, a clear indication of star formation (rather than infrared emission dominated by an active galactic nucleus; Geach et al. 2009b). Combined with the two galaxies observed with IRAM PdBI in G09, this represents an effort to obtain CO detections or limits for all the galaxies where we have detected significant emission from the polycyclic aromatic hydrocarbon 7.7$\mu$m band. The line luminosities imply star formation rates of $\sim 30–60 M_\odot$ yr$^{-1}$, thus allowing us to link molecular gas with moderate levels of dusty star formation in the galaxies.

In this Letter we present the results in the context of the broader star-forming population at $z = 0.4$, rather than focus-
ing on potential environmental effects in the cluster. We believe this is a valid approach, since these galaxies are expected to be randomly accreted onto the cluster from the surrounding field, and the galaxies are seen at a stage where strong environmental effects associated with clusters (specifically ram-pressure stripping and harassment) are yet to have an effect (Treu et al. 2003; Moran et al. 2007). They lie at clustocentric distances and are likely to be representative of disk galaxies from G09 which are included in the following analysis.

The new IRAM observations were conducted over June–October 2009 in configuration ‘D’, using 5 antennae, and we adopted the same strategy as in G09. Sensitivities ranged between 0.51–1.17 mJy (median average for 10 MHz wide channels and 2 polarisations), and the on-source exposure times ranged between 6.4–12.8 hrs. We targeted the CO (J=1→0) 115.27 GHz rotational transition at ν_{obs} ≈ 82.63 GHz in 5 sources. The 3 mm receiver was tuned to the frequency of the redshifted CO (J=1→0) line at the systemic redshift of each galaxy derived from optical spectroscopy (Czoske et al. 2000; Moran et al. 2007). As in G09, the correlator was set-up with 2.5 MHz spacing (2×64 channels, 320 MHz bandwidth). The phase and flux calibrators were the sources 3C454.3, 0119+115 and 0007+171. The observing conditions were good or excellent in terms of atmospheric phase stability, however any anomalous and high phase-noise visibilities were flagged in the calibration stage. Data were calibrated, mapped and analysed using GILDAS (Guilloteau & Lucas 2000).

3. RESULTS

3.1. Plateau de Bure CO detections

We detect CO (J=1→0) emission in three galaxies (>4σ detections within 2° of the phase tracking centre, significances determined from the integrated line flux). Velocity-integrated maps and mm-spectra are shown in Figure 1. Total fluxes are evaluated from single or double Gaussian fits to the spectra depending on whether the profiles are very broad and have hints that they are double peaked. The line luminosities are in the range L^{CO}_{1} = 0.26–0.64 × 10^{10} K km s^{-1} pc^{2} (Table 1). Uncertainties on the luminosities are estimated by re-evaluating the Gaussian fits after artificially adding noise to each channel based on the observed r.m.s. fluctuations in each data cube. Upper 3σ limits on L^{CO}_{1} for the two non-detections are based on the r.m.s. noise in the observations of each source (note that the two non-detections are also the two galaxies with the lowest SFRs in the sample). The luminosities and line widths are listed in Table 1; we also list the properties of the two galaxies from G09 which are included in the following analysis.

The spectra of MIPS J002652.5 and MIPS J002715.0, like MIPS J002721.0 (G09) exhibit broad CO (J=1→0) emission, and can be well-fit by double gaussian profiles. None of the new sample show obvious signs of major mergers or strong tidal interaction in the deep optical imaging (Fig. 1), and so we conclude that we are most likely observing CO (J=1→0) emission tracing molecular gas distributed over rotationally-supported disks.

3.2. Physical properties of the galaxies

Stellar masses for all the galaxies were determined by fitting the galaxy SED constructed from BVRIJK imaging (Moran et al. 2007) to a large suite of model SEDs using the KCorrect software, v4.2 (Blanton et al. 2007). Utilizing the known spectroscopic redshifts, KCorrect finds the best non-negative combination of the template spectra to fit the galaxy SED in its rest-frame, including a reddening law, with best-fit values covering a range A_V = 0.8–2.3 mag. Stellar masses are then calculated from the luminosity and mass-to-light ratio of the best-fitting model in the rest-frame K-band, \( \log(\frac{M_*}{\odot}) = \log(L_*/L_K) \). The fits had an average mass-to-light ratio of \( \langle \frac{M_*}{L_*} \rangle = 0.36 \) (range 0.24–0.52), and inferred stellar masses ranging over \( M_* \sim 0.5–1 \times 10^{11} M_\odot \) (Table 1).

In G09 we adopted a conservative ‘ULIRG’ conversion of \( M_*/L_* = 0.8 M_\odot / L_\odot \) for gas mass, where \( M_*(H_2 + \text{He}) = \alpha L_\odot \) (we omit the units of \( \alpha \) for clarity in the following). However, there are hints that a Galactic scaling is more appropriate for these galaxies. The first point to note is the similarity between the so-called star-formation ‘efficiencies’, measured by \( L^{CO}_{1}/L_{IR} \), compared to local quiescent disks. The disks in this sample have a mean \( L^{CO}_{1}/L_{IR} \) of 51 (range 28–73), similar to that of local spirals, but lower than that of ULIRGs, which tend to have \( L^{CO}_{1}/L_{IR} \gtrsim 100 \) (Solomon et al. 1997). Daddi et al. (2010) and Tacconi et al. (2010) report similar ‘secular’ properties for \( z > 1 \) disks, although note that these high-z observations measure \( J^{CO}_{1} > 1 \) transitions, and so require an additional uncertain correction to estimate gas mass. It is claimed that the efficiency of star-formation remains relatively constant in typical disks at all epochs (although, as a concept, star-formation ‘efficiency’ only makes sense if all of the molecular gas has an equal probability of undergoing star-formation).

Although the CO (and mid-infrared) emission is unresolved, we can evaluate how appropriate \( \alpha = 0.8 \) is based on the offset from the Kennicut-Schmidt (K-S) law (\( \Sigma_{SFR} \propto L_{IR} \))
Σ_{gas};Kennicutt 1998), assuming both gas and star-formation trace the stellar emission. Inclination and effective radii of the disks are estimated by fitting a 2D model following a Sérsic profile to a CFHT R-band image (Czoske et al. 2001), using GALFIT v3.0.2 (Peng et al. 2010). GALFIT was run on postage stamps of 20″ × 20″, simultaneously fitting models to the main galaxy and any bright companions in the field. GALFIT produces estimates of the galaxy axial ratio and size that accounts for the seeing of the ground based image, convolving with a point-spread function that we have extracted from stars in the CFHT image. The effective radii of the disks range between 0.9–1.5″ (4.8–8.1 kpc), with a mean of 1″ (5.4 kpc), and typical uncertainties of 0.02″. We take the effective radii as the size of the disks and find a mean ⟨αKS⟩ ~ 4.2, in line with a Galactic conversion. Note that this should be taken only as a guide for choosing between a Galactic and ULIRG-like conversion; αKS should not be applied as the actual calibration: it is particularly sensitive to the assumed spatial distribution of the gas and star-formation, such that a larger assumed radius would result in a larger αKS and vice versa (with r ≤ 1 kpc required for αKS ~ 0.8).

MIPS J002703.6, is partially covered by one of the sparse Hubble Space Telescope/WFPC2 (F814W) images taken of Cl0024+16 (Treu et al. 2003), revealing finer detail of the optical morphology (Figure 1). The galaxy has been typed as an early-type spiral (Treu et al. 2003), and has clear spiral structure with several bright knots of emission in the northern arm (presumably star-forming regions) and a potential bar. We have run GALFIT on the HST/WFPC2 image, where the best 2D fit is a two-component Sérsic bulge and exponential disk, where the bulge and disk have effective radii of 0.15″ (0.8 kpc) and 1.05″ (5.6 kpc) respectively (consistent with the value derived from the ground-based imaging), and the bulge-to-total light ratio is B/T = 0.031.

Based on this evidence, we now assume a Galactic conversion of α = 4.6 to estimate the gas masses, which implies molecular gas masses of M(H2 + He) = 1.2–2.9 × 10^{10}M_☉. What is the gas contribution to the total baryonic mass of these galaxies? With our choice of α, the resulting gas fractions, f_gas = M_{gas}/(M_{gas}+M_*) are in the range 0.10–0.34, with a mean of ⟨f_{gas}⟩ = 0.21 ± 0.03. We can conclude that these are actively star-forming galaxies with large gas reservoirs, but the disks are dominated by stellar mass. This is markedly different to the recently discovered z ~ 1–2 gas-rich disks of Daddi et al. (2010) and Tacconi et al. (2010), which are generally more active galaxies, with comparable stellar masses and higher gas-fractions f_gas ≥ 40%.

4. INTERPRETATION

Figure 2 shows the observed f_{gas} in M_∗ ≥ 10^{10}M_☉ galaxies at z = 0 (Leroy et al. 2008), z = 0.4 (this work) and z = 1.5–2 (Daddi et al. 2010, Tacconi et al. 2010) showing the clear decline in ⟨f_{gas}⟩ in the 10 Gyr since z ~ 2. As a guide, we cast the evolution of f_{gas} relative to the cosmological abundance of baryons in stars and molecular gas at z = 0: Ω_{H_i}/(Ω_⊙ + Ω_ *) = 0.078+0.160−0.039 from the ‘baryon census’ of Fukugita, Hogan & Peebles (1998). At z = 0, the observed f_{gas} in star-forming disks is close to that inferred from the total relative abundance of molecular gas and stars in the Universe, but at z ~ 2 it was a factor ~5–10 larger than the local value. The decline in molecular gas fraction in the stellar mass limited sample is broadly characterised by f_{gas} ∝ (1 + z)^γ, with γ ~ 1.5–2.5, shallower than the rate of decline of the average specific SFR in galaxies over the same epoch, which falls off more like (1 + z)^4 (e.g. Karim et al. 2010). This is expected, since molecular reservoirs can be replenished with fresh material via cooling; thus, it is the relative evolution of the cooling rate and star formation rate that shape the evolution of f_{gas}.

Recent semi-analytic prescriptions for galaxy formation make predictions for the evolution of the molecular ISM. In Fig. 2 we show the average H₂ + He fraction in M_∗ ≥ 10^{10}M_☉ galaxies selected in halos of various mass from the GALFORM model (galaxies populated within the Millennium Simulation ΛCDM framework). This latest model (Lagos et al. 2010) implements an empirically based star-formation law (Blitz &
Rosolowsky (2006) to estimate the molecular gas mass. The model predicts that at $z < 3$ the gas fraction is lower and the rate of decline faster for more massive halos, and at in the mass regime pertinent to the samples presented, $10^{12} M_\odot$, evolves in a way similar to the observations. The results are broadly consistent with other models. For example, in smoothed particle hydrodynamic simulations, Kereš et al. (2005) predict that the average accretion rate of gas onto galaxies within halos of $M_{\text{halo}} = 10^{12} M_\odot$ decreases from $\dot{M}_{\text{cold}} \sim 20 M_\odot \text{yr}^{-1}$ at $z = 2$ to $\dot{M}_{\text{cold}} \sim 3 M_\odot \text{yr}^{-1}$ at $z = 0.4$. The observed evolution is also consistent with the predicted cosmological evolution of the accretion rate at fixed halo mass in other models (see Dutton et al. 2010).

The evolution of $f_{\text{gas}}$ is expected to be strongly dependent on galaxy mass, since the evolution of the global average SFR appears to be halo mass dependent, as does the expected evolution of the gas accretion rate. Cooling and star formation are the key drivers of the molecular gas fraction; but it is also sensitive to the merger rate (which can deliver molecular material, trigger star-formation and reconfigure the baryonic content), feedback (heating or ejection of cold gas and $H_2$ dissociation), environmental effects (e.g. ram-pressure stripping) and growth in size of galaxy disks. The latter has an important effect since it (on average) reduces the disk hydrostatic pressure ($\propto r^2$) and therefore the efficiency of $H_2$ formation (reflected in the $H_2$/H$^+$ ratio, Elmegreen 1993; Wong & Blitz 2002), as can the metallicity and strength of the interstellar UV radiation field.

Selection effects will affect Fig. 2 severely, and we should discuss how these might affect our interpretation. Sensitivity limits do not allow us to detect galaxies with very low gas fractions at high-$z$, and in low-$z$ surveys the very gas rich systems appear to be rare. Here we have attempted to compare similar galaxies across a range of epochs, but the current sample sizes are small, and inhomogeneously selected; any conclusions we draw from Fig. 2 should be treated as indicative for future surveys that can more precisely control selection and have the efficiency to survey larger numbers.

A further caveat to note is that both Daddi et al. (2010) and Tacconi et al. (2010) apply corrections to their observed CO luminosities on account of the difference in the Rayleigh-Jeans brightness temperature of the higher $J$ transitions targeted. Tacconi et al. (2010) apply $R_{\text{J}=3\rightarrow2}$ to their CO ($J=3\rightarrow2$) luminosities (defined $R_{\text{J}=3\rightarrow2} = L'_{\text{CO}(3\rightarrow2)} / L'_{\text{CO}(1\rightarrow0)}$), and Daddi et al. (2010) apply $R_{\text{J}=2\rightarrow1}$ to their CO ($J=2\rightarrow1$) luminosities (see also Dannerbauer et al. 2009). Leroy et al. (2008) also apply $R_{\text{J}=2\rightarrow1}$ to a sub-sample of the $z \sim 0$ galaxies that were mapped in CO ($J=2\rightarrow1$). Furthermore, Daddi et al. (2010) assume an $\alpha = 3.6 \pm 0.8$, inferred from dynamical mass arguments. Although this is within $1\sigma$ of the Galactic value, assuming $\alpha = 4.6$ increases the gas fraction by $\sim 12\%$. These systematic uncertainties in CO–$H_2$ conversions should be taken as a corollary when interpreting Fig. 2, however a large change in the gas mass (or stellar mass) would be required to remove the trend in $f_{\text{gas}}$. It is unlikely that we have over-estimated the gas mass in the $z = 0.4$ LIRGs, since we have applied $\alpha = 4.6$. In the high-$z$ sources, the gas masses would have to be over-estimated by a factor $\sim 5$, or the stellar...
masses under-estimated by a factor $\sim 4$ to remove the trend.

5. SUMMARY

We have presented new constraints on the molecular gas mass of $z = 0.4$ LIRGs, showing strong evolution of $f_{\text{gas}}$ since $z \sim 2$. The observed trend encodes critical information on the evolution of the growth of galaxies, including gas accretion, feedback and stellar mass assembly. Future surveys that are able to split samples based on environment, mass, and other parameters will disentangle the relative effects that shape the evolution of the gas fraction. These observations will soon be supplemented and surpassed by progress made with the Atacama Large Millimeter Array and the Expanded Very Large Array, which will provide unprecedented sensitivity and resolution with which to probe the evolution of gas in galaxies.

This work was based on observations made with the IRAM PdBI, supported by INSU/CNRS (France), MPG (Germany) and IGN (Spain). We thank the anonymous referee for a constructive report. It is a pleasure to thank Roberto Neri for his support in this project.
