**More gestures than answers:  
Children learning about balance**

30<sup>th</sup> May 2003

revised October 2003/April 2004

Abstract

This research extends the range of domains within which children's gestures are found to play an important role in learning. The study involves children learning about balance and we locate children's gestures within a relevant model of cognitive development, the Representational Redescription Model (Karmiloff-Smith, 1992). We examined the speech and gestures of children explaining a balance task. Approximately one third of the children expressed one idea in speech and another in gesture. These children made significantly more learning gains than children whose gestures and speech matched. Children's gestures were an indicator, at pre-test, of readiness to learn and of cognitive gains. We conclude that children's gestures provide crucial insight into their cognitive state and illuminate the process of learning and representational change.

## Introduction

Developmental psychologists, when assessing children's knowledge, have long recognised the importance of listening carefully to all that a child says. Methods of statistical and discourse analysis have been refined to ensure accuracy and reliability when coding children's speech. However, when a child is asked to explain a problem-solving task, there is no way of ensuring that the child's explanation is a reliable indicator of all that the child knows. In this paper we shall argue that, although precision in attending to children's speech is important, children's articulated speech is just one component of the communicative channel. Children also convey a substantial proportion of their knowledge through another mode, the hand gestures that accompany their speech. Attending to children's gestures as well as their speech, we shall argue, offers an additional window into the mind of the child and more accuracy when assessing children's understanding (see also Goldin-Meadow & Alibali, 2002).

The theoretical and empirical motivation for this paper comes from work in two areas that address children's knowledge representations. The first comes from research investigating gesture production in children, particularly in problem solving contexts such as conservation and in understanding mathematical equivalence (e.g., Alibali & Goldin-Meadow, 1993; Church & Goldin-Meadow, 1986; Perry, Church & Goldin-Meadow, 1988). These studies provide the methodological as well as some theoretical impetus for this investigation into children's gestures. A unique contribution of the study presented here is that it extends previous empirical work by exploring children's gestures

within a domain not previously investigated, using a balance beam task. The second body of work of relevance here focuses on Karmiloff-Smith's Representational Redescription (RR) model. This model is invoked because it provides a definitive and unique account of both non-verbal and verbal representations in development and has also been applied to children acquiring a concept about balance. Furthermore, it accounts for how children can have more knowledge than they are able to talk about, and provides a developmental account of non-verbal knowledge. Therefore it offers a very plausible theoretical framework within which to understand children's gestures. This study is the first to locate gestural knowledge of the balance beam task within the RR model.

#### Gestures as a reflection of knowledge

When children, and adults, are asked to explain something they frequently gesture with their hands. These gestures are usually spontaneous and produced without conscious awareness. Research is increasingly focusing on what children's gestures can tell us about their thoughts, because children may not always accurately explain what they know. One reason for this may be that the child lacks the necessary linguistic competence to produce an explanation. This is particularly true of children with language impairments who have been found to express more sophisticated knowledge in gesture than in speech (Evans, Alibali & McNeil, 2001). On the other hand, children without any linguistic impairment may nonetheless possess knowledge that they cannot express verbally, i.e., knowledge which is implicit or encoded in a visual or spatial format (Goldin-Meadow & Alibali, 1994; Karmiloff-Smith, 1992) and it is this knowledge that may be communicated in gestural form.

Research has shown that it is possible for experienced coders to assign meaning to the gestures that children produce when solving problems. Even when making independent assessments, observers have been found to be able to interpret reliably the meaning of a gesture in the same way. This indicates that there is consistency in the way that different children gesture when they are given the same task to explain.

Interestingly, children have been found to sometimes convey different information in their gestures to that expressed in their spoken explanations (Alibali & Goldin-Meadow, 1993; Garber, 1998). For example, on the Piagetian conservation task of liquid quantity, height and width are the two key variables. Some children have been found to talk only about one variable, the height of the containers, but to accompany this with a gesture that indicates the other variable, width (Church & Goldin-Meadow, 1986). These gesture-speech mismatches have been found to indicate children who are in transition between one knowledge-state and another and there is empirical evidence to suggest that this indicates a readiness to learn.

Goldin-Meadow and her colleagues propose that gesture is a reliable index of transitional knowledge and that mismatches between gestures and speech reflect openness to instruction. Children whose spoken explanations depict different information from that conveyed by their hand gestures have been found to be significantly more likely to profit from instruction than children whose speech and gestures match (see Goldin-Meadow & Alibali 2002 for a summary). A child who produces two ideas concurrently, one in

speech and another in gesture, is indexing cognitive instability or variability. Cognitive variability has been shown to be a reliable indicator that the knowledge system is in a state of transition and ready to undergo change (Siegler, 1996). When Perry et al (1988) presented children with mathematical equivalence problems and asked those children who were failing to explain how they arrived at their answers, some children displayed some understanding of the nature of equivalence in their gestures, although not in their spoken explanations. These children, it was later found, were more likely to improve after instruction, than children who did not produce mismatches. Similarly, Church & Goldin-Meadow (1986) found that younger children who produced gesture-speech mismatches on a conservation task were also more open to instruction. The phenomenon, Goldin-Meadow & Alibali conclude, 'is not tied to one age, nor to one task' (2002, p.83).

Therefore, spontaneously produced gestures are more than just paralinguistic features and the evidence from these training studies suggests their role is not merely a communicative one. Gestures are clearly an integral component of the cognitive process and can have an effect on thought itself (McNeill, 1992). They have the potential to give insights into the multi-dimensional nature of the child's thinking processes and may reflect knowledge that the child has but which is not yet well developed enough to express verbally. Further support for this notion comes from the finding that blind babies gesture from birth and the gestures they produce resemble, in both form and content, those produced by sighted children (Iverson & Goldin-Meadow, 1997). As these children have never seen other people gesture this implies that gestures are important to the speaker as well as to the listener. In sighted people gestures are not always produced

when others are watching; for example, adults frequently gesture whilst speaking on the telephone. How gestures help the speaker is explored further when we ask whether gesturing not only reflects, but can also enhance, cognitive capacities. First, however, we introduce a new problem-solving domain within which to explore these issues and extend previous findings.

### Extending the study of children's gestures to a new domain

Balancing tasks have frequently been used as a testing ground for theories of cognitive development (e.g., Halford, 1993; Inhelder & Piaget, 1958; Karmiloff-Smith & Inhelder, 1974; Karmiloff-Smith, 1992; Pine & Messer, 1998, 1999, 2000; Siegler, 1976). Having used the balance beam task as a means of investigating children's implicit and explicit representations in our previous work we are able to draw upon this body of work to extend the range of domains within which gesture is studied. To date, empirical studies have been conducted looking at children's gestures when carrying out a conservation task (Alibali, Flevares & Goldin-Meadow, 1997; Alibali, Kita & Young, 2000; Breckinridge-Church, Kelly & Lynch, 2000; Church & Goldin-Meadow, 1986; Goldin-Meadow & Momeni-Sandhofer, 1999) or when solving mathematical problems (Alibali, 1995; Alibali et al., 1999; Alibali & Goldin-Meadow, 1993; Gerber, Alibali & Goldin-Meadow, 1998; Perry, Breckinridge Church & Goldin-Meadow, 1992), with a few studies focusing on children's counting (Alibali & DiRusso, 1999; Graham, 1999) and the Tower of Hanoi problem (Garber, 1998; Garber & Goldin-Meadow, 2002). Since balancing studies have consistently and for many years provided a reliable test-bed for theories about cognition, it will also be informative to understand the role of children's gestures within this domain

and to integrate them into a theoretical framework of how cognitive change occurs.

The balance beam task employed in our studies involves the child balancing wooden beams (similar to a wooden ruler) on a simple support, or fulcrum, and was originally reported in Karmiloff-Smith & Inhelder (1974). The beams are either symmetrical, having a wooden block at each end, or asymmetrical with a block at one end only. The symmetrical beams balance by placing them onto the fulcrum at their mid-point. The asymmetrical beams have to be placed off-centre onto the fulcrum to balance. Hence two variables are involved in completing this task successfully, weight and distance, since distance from the fulcrum has to be adjusted according to the amount of weight at each end of the beam.

It has been particularly striking to us as investigators how children seem compelled to gesture with their hands when explaining the balance beam task. Also notable is the fact that certain gestures consistently appear to accompany descriptions of particular aspects of the task. For example, when talking about distance or length, children invariably gesture with a flat hand, palm down, and a sweeping movement from the fulcrum outward. Weight, or 'heaviness', is usually indicated by closing all the extended fingers in a downward pincer movement whilst making an up and down movement of the hand over one end of the beam. Children explaining the centre position of a beam often point to the middle with the index fingers of both hands close together. The aim of this research is to establish, by examining more closely the videotapes of children explaining this task, a rigorous and valid coding scheme for the gestures produced. A second aim is to see

whether, using a pre-test/post-test paradigm, children also produce gesture-speech mismatches on this task and, if so, whether these are predictive of later learning.

### The Representational Redescription Model

Despite producing some illuminating findings about the crucial role children's gestures play in their learning, previous research has not consistently located gestures within any particular model of cognitive development. Our work aims to address that shortfall by considering gestures within the Representational Redescription (RR) model (Karmiloff-Smith, 1992) since it is one which places significant emphasis on children's non-verbal knowledge. The RR model states that much of children's knowledge begins in an implicit, non-verbal format. Development then involves the gradual emerging into consciousness of this knowledge, via various redescriptions, until it is finally available for verbal report at the last Explicit (or E3) level in the model. The RR model has been applied to many domains of children's thinking, from learning science to drawing, mathematics and theory of mind. The micro-domain to be considered here involves children's understanding of balance and employs the balance beam task employed in our previous studies and originally described in the work of Karmiloff-Smith and Inhelder (1974).

Many young children (4-5 years) are good at the balance beam task and can balance both types of beam successfully. However, they frequently are unable to explain their success or to state any of the rules underlying the concept of balance. In fact, when asked to explain how they managed to get a particular beam to balance these children will

typically say, "I don't know, I just did it!" They are, according to the RR model, at the Implicit level. They have achieved behavioural mastery but their knowledge is still represented in a procedural, non-verbal format.

From these implicit procedures the cognitive system detects regularities and begins to abstract a central tendency, or rule, in order to begin building an abstract knowledge system. This is the process of representational redescription postulated to occur in response to an internal drive for understanding and cognitive control. Initially, a theory or rule is abstracted from the implicit procedures, and this is evident in the first explicit level of the RR model, Level E1. On the balance beam task, rule driven Level E1 behaviour is seen in the majority of 6-7 year old children; for example Pine & Messer (1999) found that of 168 five to nine-year olds tested on the balance beam, 80 children held a 'centre theory' as described by the model. When given the beams to balance, these children are successful with the symmetrical beams but not with the asymmetrical beams. They place all types of beam on to the fulcrum at their mid-point and, when the asymmetrical beams tip off, will often dismiss these as 'impossible to balance'. The children have abstracted a rule that 'all things balance in the middle' and they over-apply this rule to all instances, causing them to fail on the asymmetrical beams (Karmiloff-Smith & Inhelder, 1974). The RR model states that this level is still non-verbal although we have found Level E1 to consist of 2 levels. One is when the child's centre theory is non-verbal (this we have termed Abstraction Non-Verbal) and another is when the child can articulate their theory (the Abstraction Verbal level) (Pine & Messer, 1999, 2000, 2003). These have been found to be two distinct levels empirically with different levels of conscious access and

receptivity to instruction (Pine & Messer, 2000, 2003).

After Level E1 Karmiloff-Smith claims the representations are redescribed again, this time into Level E2 format, when knowledge becomes consciously accessible but is not yet coded in a linguistic format (nor may it ever be). This level appears to be driven less by empirical data and more by the need to incorporate into the model the feasibility of some consciously accessible spatial, kinesthetic or other non-linguistically coded representations (Karmiloff-Smith, 1992, p.23). To date the empirical evidence for Level E2 knowledge is limited and it still remains the most speculative aspect of the model. Indeed, we would question whether a consciously accessible but non-verbalisable representation could follow E1, given that we have found children who can verbalise their E1 knowledge. However, it has been suggested that children's gestures could reflect other spatial, non-verbal knowledge that is not available for speech (Goldin-Meadow & Alibali, 1994). Furthermore, "Because the representational formats underlying gesture are mimetic and analog, rather than discrete, gesture permits speakers to represent ideas that lend themselves to these formats (e.g. shape, size, spatial relationships) - ideas that, for whatever reason, may not be encoded in speech" (Goldin-Meadow, 2002, p.1400 -1401).

The final level in the RR model is Level E3, characterised by success and verbal explanation. On the balance beam task children who have reached this level can balance both types of beam on the fulcrum and explain how they balance. In their verbal explanations these children show understanding of the compensatory function of the weight and distance variables. They might say when explaining how they balanced an

asymmetrical beam, for example, "I had to make this side much longer because it doesn't have as much weight as the other side, so the longer side here will make up for the extra weight here". This type of E3 representation also allows greater cognitive flexibility (Implicit level procedures, though successful, are context bound and inflexible) and the transfer of knowledge to other domains (Pine & Messer,2003); in short, at Level E3 the RR process is complete and the child has full conceptual understanding.

The RR model is silent about the role of gestures in this redescription process from implicit procedures to conceptual understanding. However if, as the evidence presented here suggests, gestures reflect ideas that are not well formed enough to express in words it seems highly likely that emerging knowledge that is at one of these levels will be conveyed in the children's gestures. Goldin-Meadow & Alibali (2002) point out that "gestures convey knowledge that learners have not yet integrated into their explicitly acknowledged view of a problem" (p.82). Thus, in children whose knowledge has not yet reached level E3 but is still in the process of emerging, gestures may provide a window into their thoughts. We set out to test this by re-analysing videotapes of children explaining the balance beam task, when their knowledge had not reached Level E3 but had been coded at one of the earlier levels of representation.

This earlier study (Pine & Messer, 2000) set out to test the effect of different types of intervention on children's representations about the balance beam task. We found significant improvements when children observed an adult modelling the correct solution and were encouraged to explain what they saw. In general, children in this condition

showed greater learning gains than children who simply observed a model but did not produce an explanation. However, although the overall difference between the groups was significant, there were nonetheless some children in the more facilitative condition that failed to improve. There were also a number of children in the less facilitative condition that seemed to show some learning gains. In this reanalysis of the videotapes we set out to see whether the gestures that the children produced at pre-test could have been predictive indicators of the children's differential ability to benefit from the intervention. We therefore submitted the videotaped data to detailed re-analysis, using a computer based Observer system and transcribing all the gestures and speech the children produced at pre-test. If children produced gesture-speech mismatches at pre-test, and if this indicates a readiness to learn, these children would be expected to benefit more from the intervention, even when the intervention conditions are less than optimal, than children whose gestures and speech matched at pre-test.

In summary the aims of this study are:

- To establish a reliable and valid coding scheme for assigning meaning to the gestures that children produce when explaining the balance beam task.
- To identify gesture-speech mismatches on the balance beam task and verify empirically whether these predict later learning
- To locate gestural knowledge within a theoretical framework of knowledge representation and development, based on the RR model

## Method

### Design

In the original study a pre-test, treatment phase and post-test design was employed. The treatment phase had two conditions with a between subjects design; the Observe Only and the Observe and Explain condition. A further between subjects variable to be investigated here is whether the child was discordant (produced gesture-speech mismatches) or concordant (produced gesture-speech matches) at pre-test. The dependent variable is the amount of pre- to post-test improvement in ability to balance beams or in representational level.

### Participants

One hundred and forty children from two Hertfordshire mixed infant/junior schools participated in the pre-test. They ranged in age from 5 to 9 years. There were 61 boys with a mean age of 84.8 months, and 79 girls, mean age 83.83 months.

### Materials

For the pre- and post-test 8 wooden balance beams were used:

- 4 symmetrical beams: two without blocks, one with a block on either end, and one made by overlapping two flat beams. All of these balanced at their geometric center.
- 4 asymmetrical beams: one with one block at one end, and three with two blocks at each end but varying in thickness and length. All of these balanced off-center.

For the treatment phase the experimenter modeled one symmetrical beam (without blocks) and one asymmetrical beam (with two blocks at one end). A Panasonic V.H.S. video camera was used to record all sessions and the gestures identified in these videotaped data are the subject of the data analysis reported here.

### Procedure

In the original study the children were taken individually to a quiet area of the school. They were seated at a table next to the experimenter. After introductions they were told, "Today we are going to be talking about balancing and playing some balancing games. Do you understand what 'balancing' means? What do we mean when we say that something balances?" This was to introduce the context of the task and ensure that children had encountered the term balance before. The experimenter then explained that they would be trying to get some wooden beams to balance on the fulcrum, which was indicated to the children. Children were told that the aim was to make each beam stay level on the fulcrum so it did not tip off to one side or the other.

#### Pre-test

The fulcrum was placed before the child, and each child was asked, "Can you see if you can make the beams stay level on this bar here? That is, make them balance without falling off?" The child attempted the beams one at a time and the experimenter encouraged the child to give explanations about how each beam balanced or, if it would not, the reason why not. This was done by asking the child after success, "How is that one balancing?" "What do you have to do to make it balance?" or "How did you do that?" Similarly, if a child failed to balance a beam, questions were posed such as, "Why won't it balance?" "What did you do to try and get it to balance?" or "Do you think it can be balanced? ".

#### Treatment phase

Having attempted each of the beams, the child was then randomly assigned to one of the two conditions. In all, 53 children experienced the Observe Only (OO) condition and 47 the Observe and Explain (OE) condition.

Observe only. In this condition when the pre-test had been completed the experimenter told the child, “ Now I am going to balance some beams and I would like you to watch carefully how I do it, then you can have another turn at balancing them.” The experimenter showed the child how to balance the symmetrical beam and the asymmetrical beam. The child was not invited to comment or attempt to balance the beams.

Observe and Explain. In this condition the experimenter told the child, “Now I am going to balance some beams and I would like you to watch carefully and try to tell me how each one balances on the bar. Then you can have another turn at balancing them.” The experimenter showed the child how to balance the two beams and invited the child to comment on how this was done. During this session the children did not themselves attempt to balance the beams.

Post-test. The child was once again asked to balance each of the beams on the fulcrum, as in the pre-test, and questions were asked to probe the child’s understanding and to encourage explanations.

There was then a short de-briefing session when the experimenter answered any questions the children had, praised and thanked them. Each child’s performance during the session was recorded on a data sheet by the experimenter and also videotaped.

Analysis of a child’s balance beam performance at pre- and post-test enabled the classification of each child into one of the following representational levels (with their correspondence to the original Karmiloff-Smith levels in parentheses):

Implicit (I): the child is able to balance at least two of each type of beam (symmetrical and asymmetrical), but has no consistent strategy for balancing or for initially placing a beam onto the fulcrum. In addition the child is unable to offer an

explanation for his or her success (e.g., says “Don’t know” or “I just did it”), or explanations fail to include a mention of the relevant variables, weight and distance.

Implicit Transition (transition from I to E1): the child is able to balance no more than one of each type of beam, but places all beams onto the fulcrum around their mid-point. Explanations are similar to those at the Implicit level (see above).

Abstraction Non-Verbal (E1): the child is able to balance at least two symmetrical beams but fails on all, or all but one, of the asymmetrical beams. There is clear evidence of a center strategy, with all beams being placed onto the fulcrum at their mid-point. The child may state that asymmetrical beams cannot be balanced but does not explain a center theory.

Abstraction Verbal (E1): performance is equivalent to Abstraction Non-Verbal level (see above) but explanations include reference to the center strategy (e.g., says, “You have to put it in the middle”).

Explicit Transition (transition from E1 to E3): the child is able to balance at least two of each type of beam and is able to explain a strategy for balancing both types. For example the child might say, “You have to put this in the middle,” for a symmetrical beam, or, “You have to put this one a bit more over to the side,” for an asymmetrical beam. However, there is no explanation of the function of the two relevant variables, weight and distance.

Explicit E3 (E3): The child is able to balance at least two, and usually all, of each type of beam and explanations include reference to the compensatory function of the

two variables, weight and distance. For example the child might say, “This side’s got more weight on so I make this side longer so that it has the same weight”.

(In the study described, children at Level E3 did not continue after pre-test as there was little scope for improvement. However, the coding scheme for speech and gestures was based on the performance of these children).

This system of classification is derived from Karmiloff-Smith's Representational Redescription model (1992), with modifications based on empirical findings from our own research with over 300 children (Pine & Messer, 1998; 1999; 2003). The Implicit and Explicit E-3 Levels correspond to those identified by Karmiloff-Smith. Level E1 has been replaced by two levels: Abstraction Verbal and Abstraction Non-Verbal. Additional transition levels have been identified through previous work and incorporated into the model, although no evidence for Level E2 has been found. This was described by Karmiloff-Smith (1992) as a level of representation prior to reaching Level E3 that is consciously accessible but non-verbalisable. Our studies have shown that verbalization of some knowledge is evident by the time children are approaching Level E3, indeed from the Abstraction Verbal level onwards. These revised levels have been the subject of validation by two independent raters, with inter-rater reliability exceeding 90% (Pine & Messer, 1999). Longitudinal testing has confirmed the hierarchical ordering of the levels, with children tending to progress from Implicit through the Abstraction levels and on to Level E3 as their understanding of the task becomes more explicit (Pine & Messer, 2003).

#### Coding of gestures

In the original study the children were classified at a level of representation at pre-test and improvement assessed via a pre- to post-test change in representational level, from a lower to a higher level within the scheme outlined above. The Observe Only condition

was found to produce improvement in 50% of the children, the Observe and Explain produced improvement in 70% of the children. It was concluded that the Observe and Explain condition was the more helpful to the children in terms of learning gains, based on analysis of the children's performance and explanations at pre and post-test and being at a higher level of representation at post-test than at pre-test. For this study the videotapes were re-analysed with the focus on the children's gestures at pre-test to see whether these shed further light on the mechanisms producing cognitive change. After all, half the children in the less facilitative condition still improved and almost a third of the children in the more helpful condition failed to improve. By looking at the gestures the children produced we aim to be able to explain the differential ability to benefit from the intervention.

#### Devising the coding scheme

The existing videotapes were analysed with the aim of producing a valid and reliable coding scheme for the gestures produced by the children. Initially children were identified who were able to balance all types of beam and who were producing the correct verbal explanations, i.e. children at the highest level (E3) in the RR model's coding scheme. There were 41 children at this level in total. They completed the pre-test only and were then excluded from the rest of the experiment as further learning was unlikely. Their correct verbal explanations were found to consistently include descriptions of one or more of three variables: weight, distance, and middle. In other words, the children spoke about the weight or weights on either side of the beam, the distance of the weights from the fulcrum (particularly with an asymmetrical beam that was placed off-centre) or the importance of placing a beam in the middle (particularly for

symmetrical beams). The gestures that regularly accompanied these verbal descriptions were identified as followed:

Weight – the child closes all fingers together so they are pointing downwards and moves the hand up and down over one end of the beam.

Distance – the child moves their hand from the fulcrum to the end of the beam. Their hand is either completely flat or clenched with one finger pointed out. The palm faces downwards and the movement is from side to side.

Middle – the child points at the middle of the beam on the fulcrum with one or both hands.

Reliability was established by having a second observer view a proportion (approximately 45%) of the videotaped sessions and code the children's gestures that accompanied correct explanations. The first rater identified a range of concordant explanations within these sessions, that is where the spoken explanation given matched the gesture the child produced. Ten of these explanations included middle, seven included weight and nine included distance. Inter-rater reliability was 98 % agreement between the two coders for describing gestures that most frequently accompanied correct explanations. This coding scheme was then used to code the remaining 99 participants' gestures.

#### Identifying discordant and concordant children

Next the focus shifted to the 99 remaining children as they attempted each beam at pre-test. These children were at one of the other levels in the classification system i.e. not yet

at Level E3 and many were unable to balance some or all of the beams. All videotaped data were transcribed for gesture and speech, according to any variables (weight, middle or distance) that were being conveyed. Speech was coded by turning off the video picture and listening to the audio portion of the tape only, to ensure that the experimenter could not be influenced by the presence of any gestures. The videotape was then re-run with the picture on but the sound turned off, and the children's gestures were coded in isolation from their spoken explanations. The next step involved comparing the spoken with the gestured variable and classifying the children as either concordant (gesture-speech matching) or discordant (gesture-speech mismatching).

Children were classified as concordant if their gestures were coded as expressing the same information as their speech<sup>1</sup>. Children were categorised as discordant if they produced a gesture that was coded differently to their speech. For example, a discordant child might explain that a beam balances 'because it is in the middle' yet might accompany this with a weight or distance gesture.

It was hypothesised that children classified as discordant would make a greater improvement on the balance beam task from pre-test to post-test than the children who were classified as concordant.

## Results

---

<sup>1</sup> Children were also classified as concordant if they spoke without gesturing (as Goldin-Meadow, Nusbaum, Garber & Church (1993), although there were only 3 such children in this study.

Children were classified as discordant if they produced at least one gesture-speech mismatch at pre-test or concordant if their gestures and speech matched. Of the 99 children who completed all parts of the study 36 were classified as discordant and 63 as concordant. In this section the effect of concordance and discordance on improvement is measured first as a change to a higher level of representation from pre- to post-test, then as an increase in the number of asymmetrical beams balanced at pre- and post test. In the third section we examine the relationship between producing concordant or discordant gestures and the child's level of representation.

The effect of gesture-speech match and mismatch on improvement in pre- to post-test representational level.

Here improvement is measured by a change to a higher level of representation from pre- to post-test and is a dichotomous categorical dependent variable (improve/not improve). Almost 50% of the concordant children improved, and of the smaller group of discordant children 78% improved.

These frequencies were analysed by Chi Square and a significant association between concordant/discordant gestures at pre-test and improvement at post-test was found,  $X^2(1, N = 99) = 6.98, p < .01$ .

However, the children who produced concordant and discordant gestures had not all experienced the same intervention between pre- and post-test. Of the 63 concordant

children, 29 had experienced the Observe and Explain Condition and 34 the Observe Only Condition. Of the 36 discordant children, 18 had been in each condition.

Therefore, next it was of interest to examine the association between pre-test concordance/discordance and post-test improvement, according to each of the conditions. A log-linear analysis of the three way term Condition x Classification x Improve/Not Improve was conducted but did not reach significance (LR  $X^2 = 0.04$  ns). Next, chi square analyses of the separate associations between condition and improvement and classification and improvement were conducted. Table 1 shows the number of concordant and discordant children improving and the condition experienced between pre- and post test. Children in the Observe and Explain condition were more likely to improve than not. This endorses the finding of the earlier study (Pine & Messer, 2000) that this condition was most likely to be associated with improvement. Chi square analysis found no association between concordance/discordance and improvement, both types of children were likely to improve under this more facilitative condition  $X^2(1, N = 47) = 2.40$  ns. However, even in this group 83% of the discordant children improved compared to 62% of the concordant group. Interestingly, this differed for the Observe Only condition, the condition found to be less helpful in bringing about improvement. Whilst only 50% of the children improved in this condition, amongst the discordant children this figure reached 72% whilst for the concordant children it was just 41%. Chi square analysis found this association between concordance/discordance and improvement was a reliable one  $X^2(1, N = 52) = 4.11$   $p < .05$ . This suggests that the Observe Only condition was least likely to

help those children who were concordant, and children who were discordant children fared better in the face of the less than optimal intervention.

2. Measuring improvement by gains in ability to balance asymmetrical beams.

The above analyses measured whether children improved from pre- to post-test in terms of the level of representation they were classified at. It was also considered of interest to look at a behavioural measure that yield quantitative data, i.e. the number of asymmetrical beams balanced at pre- and post-test. Since these beams are the most difficult for children to balance when they first attempt the task this is the measure that shows the greatest scope for improvement. For example, many children balance symmetrical beams at pre-test but fail to balance asymmetrical beams because they try to get them to balance at the centre rather than positioning them off-centre. After seeing these beams balanced, and particularly after being encouraged to talk about how they balance, many children subsequently succeeded with some or all of the asymmetrical beams at post-test.

A mixed Analysis of Variance (ANOVA) was conducted with the number of asymmetrical beams balanced at pre- and post-test as the repeated measures dependent variable and Pre-test Classification (Concordant, Discordant) and Condition (Observe Only, Observe & Explain) as the between subjects factors. The means for each group are given in Table 2. There was a main effect of pre- to post test change,  $F(1, 95) = 116.40$

$p = < .01$ , with all children showing pre- to post-test improvement in ability to balance asymmetrical beams. There was a main effect of Classification,  $F(1, 95) = 4.75$   $p = < .01$  but no main effect of Condition,  $F(1, 95) = .00$  ns. There was a reliable pre/post-test x Condition x Classification interaction,  $F(1, 95) = 4.59$   $p < .05$ , indicating that children's ability to benefit from the intervention condition differed according to whether or not they were classified as concordant or discordant at pre-test. The Observe and Explain condition was most likely to be associated with improvement, as was being discordant at pre-test, and it appeared that the worst case for children was to be concordant at pre-test and experience the Observe Only condition.

### 3. Association between representational level and concordance/discordant

Of further interest is the level of representation the children were classified at, and the type of gesturing associated with each of the levels. One prediction from the characterisation of the levels of the RR model is that once a child has reached a level then concordance would be achieved, i.e. with a unitary level of representation. Children in transition between levels, however, might be expected to be more discordant, as they consider more than one hypothesis and possibly entertain multiple representations before settling on one. Since our coding scheme included 2 transition levels it was of interest to see whether these produced the highest rates of discordance. The Explicit Transition level did feature twice as many discordant than concordant children, a pattern that was the converse of that found overall and that fitted with our prediction. This was not the case

with the Implicit Transition level, where there were three times as many concordant as discordant children. Although the numbers at some of the levels were low, with the majority of children being at one of the Abstraction levels (either verbal or non-verbal), it can be seen from Table 3 that discordance could be detected at all levels and was not just confined to the transition levels. A Chi square analysis of these frequencies confirmed that there was no reliable association between representational level and concordance/discordance,  $X^2(4, N = 99) = 5.15$  ns.

## Discussion

One of the aims of this study was to establish a reliable and valid coding scheme for assigning meaning to the gestures that children produce when explaining the balance beam task. It was found that children's verbal and gestural explanations fell into three distinct categories, relating to three dimensions of the task: weight, distance or middle. High inter-rater reliability confirmed that these could be reliably coded and the coding scheme was used to classify 99 children's speech and gestures on the balance beam pre-test.

A further aim was to identify gesture-speech mismatches and verify empirically whether these predict knowledge change in response to being exposed to someone modeling the solution. Having coded children's speech and gestures at pre-test it was possible to identify children who, when producing an explanation about the task, indicated one variable in speech and another in gesture. These children were classified as discordant. Children whose speech and gestures matched were classified as concordant. Just over one third of the sample of children were classified as discordant. When the improvement from pre-to post-test was analysed, both in terms of improved competence in balancing asymmetrical beams and improved understanding in terms of the representational level, it was found that there was a reliable association between being discordant at pre-test and subsequent post-test improvement. This supports the hypothesis that children in a discordant state are ready to learn and that their gesture-speech mismatches predict later

learning. It was also found that discordant and concordant children differed in their ability to make use of the intervention experience. We had previously shown that the condition in which children observed a model and explained what they saw (Observe and Explain) was more facilitative than a condition in which children merely observed but did not explain (Observe Only) (Pine & Messer, 2000). By re-analysing these data to see whether concordance/discordance was a mediating factor in the learning process, it was found that those children who did improve despite being in the less helpful condition were more likely to have been discordant at pre-test. So discordant children fared better, even when the intervention condition was less than optimal, the Observe Only condition. Thus the worst outcome was for many of the children who were concordant at pre-test and who experienced the Observe Only condition. Since the concordance of many of these children indicated they were not open to instruction only the most optimal learning conditions would have had a chance of inducing change. When this was not provided these children were likely to remain at the same state of learning they were in when the study began, as indeed the majority of concordant children in the Observe Only condition did.

These findings are by no means conclusive and can only reflect the general trend found in these data. There were still a few children who were discordant who failed to improve, or who were concordant and improved, but the fact that these were the least likely associations suggests that these findings are of importance and that assessing children's gestures can be informative about their readiness to learn. This study is also an example of how failing to take account of children's gestures means that an important source of

information is overlooked. Looking at the concordance or discordance of their gestures has been found to explain why some children improve and others do not when given the same learning conditions. For example, in our previous study we found that the Observe & Explain condition produced learning gains in most of the children, but there were still 14 children who failed to improve. By looking at these children's gestures we now see that more than three times as many of those non-improvers were concordant than discordant. Learning intervention studies rarely produce 100% success and measures of effectiveness are frequently based on whether the majority of children benefit or not. Looking at children's gestures, as a means of identifying children who are ready to learn, offers insight into the differential outcomes of these studies and extends our knowledge about why some children respond to intervention and others do not.

During this study it was noted that sometimes children appeared to first display an idea in a gesture before they were able to express it verbally. This has important practical and educational implications. An adult who is interacting with the child may use these gestural signals as a way of interpreting the child's knowledge state. If an adult can detect when a child is ready to learn, indicated by gesture-speech mismatch, they may modify the way that they interact with the child. There is evidence to suggest that most adults, and not just those involved with teaching children, attend to gestures when assessing what children know (Alibali, Flevares & Goldin-Meadow, 1997; Goldin-Meadow & Sandhofer, 1999; Pine, 2003). Furthermore, adults are not just sensitive to the gestures that children produce; they may even modify the information they provide to the child accordingly. Goldin-Meadow & Singer (2003) have shown that adults teach a wider

range of problem-solving strategies to children who are producing mismatches, than to those who are not.

It is therefore possible that the first 'point of exit' for a child's newly emerging knowledge may be via their hand gestures. These send a reliable signal to an interactive partner about the child's cognitive state and when they are on the verge of a new insight, or their zone of proximal development, as first described by Vygotsky (1978). Adults can then respond to those cues with the most appropriate instruction and, as a result, the child has successfully shaped their own learning environment.

Finally, we sought to locate gestural knowledge within a theoretical framework of knowledge representation, based on Karmiloff-Smith's (1992) Representational Redescription model. This model was invoked because we had already established a means of coding children at most of the levels of the model on the balance beam task, based on extensive previous work (Pine & Messer 1999, 2000, 2003; Pine et al., 1998, 2002). But more importantly, it is one model that takes accounts of children's non-verbal knowledge and we hoped to establish whether this knowledge was detectable in the children's gestures. The results at each level of representation were interesting but somewhat equivocal. One hypothesis was that discordance would be more likely to appear at transition levels, i.e. when the child was in transition between the Implicit and E1 (Abstraction) levels, or between E1 (Abstraction) levels and E3. This was not found to be the case, since at every level a number of children exhibited discordance between their speech and gestures. This casts some doubt about the conceptual stability of these

representations and suggests that each level may not be a unitary representation and, in fact, encompasses more than just a single idea. In terms of the nature of cognitive representations it tells us that cognitive variability, as manifested by gesture-speech mismatches, occurs at all stages of the knowledge acquisition process. Even when knowledge appears to be in a rigid, theory-driven representational state (such as Level E1 or, as depicted here, the Abstraction levels) there will be times when the child is also entertaining an alternative hypothesis and this may 'leak' out in gesture.

Thus, although it has been hard to find empirical evidence for Level E2 as Karmiloff-Smith describes it, her notion that knowledge can be in the system at a conscious, though non-verbalisable level, has considerable credence. Observations of the nature of children's discordance in this study suggested that children may gesture knowledge that they were unable verbalise. In other words, their gestures may be in advance of their speech or information may be conveyed uniquely in gesture (i.e. never appear in their speech). We are now conducting microgenetic analyses of such mismatches in order to determine more accurately the degree of temporal and semantic synchrony between children's speech and gestures (Pine, Lufkin & Messer, 2004).

This leads us to conclude that the elusiveness of Level E2 is due to Karmiloff-Smith's conceptualization of it as a level of representation *per se*. The notion of knowledge that is in the cognitive system at a conscious but non-verbalisable level may be more plausibly viewed as a pervasive characteristic of the redescription process, rather than a level *per se*. Our data revealed no reliable association between representational level and

concordance/discordance. In other words, whilst children are at any of the other levels of representation, they may have knowledge that is consciously accessible and that leaks out in gesture before it is verbalisable. Whilst failing to shed further light on Level E2, this finding does speak to the dynamic nature of knowledge development and the crucial role that variability plays continuously in the learning process (see Siegler, 1996). It also extends Karmiloff-Smith's (1992) conjecture regarding the RR model being based on a multi-representational system and provides empirical support for this notion. Gestures may even play a role in triggering representational redescription from one level to the next, an issue about which the model has hitherto been relatively silent.

In summary, an important contribution of the research presented here has been to extend the range of domains within which children's gestures have been shown to play an important role in learning. McNeill (1992) describes gestures as 'microgenetically evolving representations' (p.250) and these findings endorse this notion of gestures as an integral part of the child's thinking processes. The children in this study were found to express meaningful information in gesture, and over one third of them conveyed different information to that expressed in their speech. Moreover, as well as reflecting the children's emerging knowledge, their gesture-speech mismatches were also found to be a reliable indicator of their receptivity to instruction and their ability to make use of different learning conditions. We conclude that gestures are an important research tool for assessing children's knowledge and for illuminating the process of learning.

Table 1: The number of discordant/concordant children who improved from pre- to post-test in representational level according to the condition experienced.

CONDITION	OBSERVE AND EXPLAIN		OBSERVE ONLY	
	Concordant	Discordant	Concordant	Discordant
Pre-test classification				
Improve	18 (62%)	15 (83%)	14 (41%)	13 (72%)
Not improve	11 (38%)	3 (17%)	20 (59%)	5 (28%)

Table 2: The mean number of asymmetrical beams balanced by children at pre- and post-test, according to gesture-speech classification and condition.

Classification:	CONCORDANT	DISCORDANT
Condition:		
OBSERVE & EXPLAIN	n = 29	n = 18
Pre-test	M = 1.24 (sd = 1.18)	M = 1.88 (sd = 1.36)
Post-test	M = 2.89 (sd = 1.29)	M = 3.55 (sd = 1.04)
OBSERVE ONLY	n = 34	n = 18
Pre-test	M = 1.44 (sd = 1.30)	M = 1.22 (sd = 1.16)
Post-test	M = 2.44 (sd = 1.46)	M = 3.55 (sd = 0.78)

Table 3: Number of children classified as discordant/concordant at pre-test according to representational level.

<b>Representational level at pre-test</b>	<b>Concordant</b>	<b>Discordant</b>
Implicit	<b>9</b> (64%)	<b>5</b> (36%)
Implicit Transition	<b>6</b> (73%)	<b>2</b> (25%)
Abstraction Nonverbal	<b>17</b> (68%)	<b>8</b> (32%)
Abstraction Verbal	<b>25</b> (62%)	<b>15</b> (38%)
Explicit Transition	<b>4</b> (33%)	<b>8</b> (67%)
