## ABSTRACT

The star formation history of nearby early-type galaxies is investigated via numerical modelling. Idealized hydrodynamical N-body simulations with a star formation prescription are used to study the minor merger process ( $1/10 \leq M_1/M_2 \leq 1/4$ ;  $M_1 \leq M_2$ ) between a giant galaxy (host) and a less massive spiral galaxy (satellite) with reasonable assumptions for the ages and metallicities of the merger progenitors. We find that the evolution of the star formation rate is extended over several dynamical times and shows peaks which correspond to pericentre passages of the satellite. The newly formed stars are mainly located in the central part of the satellite remnant while the older stars of the initial disk are deposited at larger radii in shell-like structures. After the final plunge of the satellite, star formation in the central part of the remnant can continue for several Gyrs depending on the star formation efficiency. Although the mass fraction in new stars is small, we find that the half-mass radius differs from the half-light radius in the V and H bands. Moreover synthetic 2D images in J, H, NUV,  $H_\beta$  and V bands, using the characteristic filters of the Wide Field Camera 3 (WFC3) on the Hubble Space Telescope (HST), reveal that residual star formation induced by gas-rich minor mergers can be clearly observed during and after the final plunge, especially in the NUV band, for interacting systems at ( $z \leq 0.023$ ) over moderate numbers of orbits ( $\sim 2$  orbits correspond to typical exposure times of  $\sim 3600$  sec). This suggests that WFC3 has the potential to resolve these substructures, characterize plausible past merger episodes, and give clues to the formation of early-type galaxies.

**Key words:** galaxies: formation - galaxies: interactions - galaxies: structure - galaxies: kinematics and dynamics - galaxies: photometry - methods: N-body simulations

## 1 INTRODUCTION

The formation and evolution of early-type galaxies (hereinafter ETGs) remains an outstanding puzzle in contemporary astrophysics (see Cimatti 2009 for a recent review). According to earlier studies, ETGs seem to form a class of objects with simple and well defined properties: they tend to have a smooth morphology, an old stellar population, a red optical colour and are free of cold gas and ongoing star formation (Searle, Sargent

& Bagnulo 1973; Larson 1975). However, this classic picture is challenged by recent observations. For instance, the presence of cold gas and dust as well as evidence of recent star formation has been detected in several systems (see, for instance, Goudfrooij et al. 1994; Macchetto et al. 1996; Trager et al. 2000; Yi et al. 2005; Morganti et al. 2006; Kaviraj et al. 2007; Sarzi et al. 2008, Clemens et al. 2009b), and the associated star formation rate can even be comparable to that in normal spiral galaxies although these events are rather rare (Fukugita et al. 2007). Moreover, recent studies based on GALEX (Galaxy Evolution Explorer) near-UV photometry of a

\* E-mail: peirani@iap.fr

large sample of ETGs found that 30% of them experience ongoing or recent star formation (Schawinski et al. 2007; Kaviraj et al. 2007), and a similar trend has been obtained from mid-infrared Spitzer data in the Coma and Virgo Clusters (Bressan et al. 2006; Clemens et al. 2009a) or from the COSMOS survey (Kaviraj et al. 2010).

Understanding the formation of early-type galaxies, and in particular their star formation history, is of crucial importance for setting strong constraints on models of galaxy formation. As has been widely discussed in the literature, there are currently two competing scenarios for the formation of ETGs. On the one hand there is the *monolithic collapse* model in which galaxies are formed in short, highly efficient starbursts at high redshift ( $z \gg 1$ ) and evolve purely passively thereafter (Eggen, Lynden-Bell & Sandage 1962; Larson 1974; Arimoto & Yoshii 1987). On the other hand, the *hierarchical structure formation* model suggests that the most massive galaxies are formed from successive mergers of smaller entities with accompanying star formation over a cosmological time-scale (Toomre 1977; Blumenthal et al. 1984; Kauffmann, White, & Guiderdoni 1993). Although these models are in good agreement with some aspects of observational data, they both face some problems. For instance, the monolithic model is supported by the existence of, and small scatter in, galaxy scaling relations such as the colour-magnitude relation (Sandage & Visvanathan 1978), the fundamental plane (Djorgovski & Davis 1987; Jorgensen, Franx & Kjaergaard 1996; Saglia et al. 1997) and the Mg- $\sigma$  relation (Colless et al. 1999; Kuntschner et al. 2001), but cannot easily explain the residual star formation and cold gas found in ETGs. As far as hierarchical models are concerned, although they predict galaxy interaction, they are in disagreement with the so-called “down sizing” phenomenon. Indeed, observations of deep surveys ( $z \geq 1 - 2$ ), such as the Las Campanas Infrared Survey, HST Deep Field North and Gemini Deep Deep Survey (GDDS) have revealed an excess of massive early-type galaxies undergoing “top-down” assembly with high inferred specific star formation rates relative to predictions of the hierarchical scenario (Kodama et al. 2004; Glazebrook et al. 2004; Cimatti, Daddi & Renzini 2006).

It is now well known that ETGs have considerable substructure (e.g. from SAURON and GALEX) which is interpreted as a result of mergers in the past several gigayears. To study this plausible process, we have compared the ultra-violet (UV) colours of nearby ( $0.05 \leq z \leq 0.06$ ) early-type galaxies with synthetic photometry derived from numerical simulations of minor mergers, with reasonable assumption for the ages, metallicities and dust properties of the merger progenitors (Kaviraj et al. 2009, hereafter K09). We found that the large scatter in the ultra-violet colours of intermediate mass early-type galaxies in the local universe and the inferred low-level recent star formation in this objects can be reproduced by minor mergers in the standard  $\Lambda$ CDM cosmology. In the present work, our aim is to study the evolution of the internal structure of these objects using the same methodology but with higher mass resolution, in order to help understand in more

detail the observational signatures of satellite minor merger events with different mass ratios, gas-fractions and orbital configurations. This work is also motivated by the recent installation on the Hubble Space Telescope (HST) of NASA’s Wide Field Camera 3 (WFC3<sup>†</sup>) whose optical design provides a large field of view and high sensitivity over a broad wavelength range, excellent spatial resolution and a stable and accurate photometric performance. It features two independent imaging cameras, a UV/optical channel (UVIS) and a near-infrared channel (IR). Both channels are equipped with a broad selection of spectral filters and some of these have been considered in our study in order to identify disrupted satellites and trace the history of the merger process.

This paper is organized as follows: in section 2 we summarize the numerical methodology that we have developed to produce WFC3 synthetic images; in section 3 we present results on the star formation history of nearby ETGs, while the last section presents our conclusions.

## 2 NUMERICAL METHODOLOGY

### 2.1 Simulations

The numerical methodology used in the present paper is described in detail in K09 where we refer the reader for more information. For the sake of clarity, we summarize the main steps below.

Our aim is to study minor mergers between an elliptical galaxy (E) and a satellite (spiral galaxy) using idealised N-body+SPH simulations. Both galaxies are created following Springel, Di Matteo & Hernquist (2005). First, the elliptical is modelled using a spherical dark matter (DM) halo and a stellar component, with a total mass of  $10^{12} M_{\odot}$ . Stars contribute 4% of this value in agreement with recent observational studies (see for instance, Jiang & Kochanek 2007; McGaugh et al. 2009). A Hernquist profile reproduces the de Vaucouleurs  $R^{1/4}$  surface brightness profiles of typical elliptical galaxies. The effective radius of the projected brightness is  $r_e = 4.29$  kpc. As far as the satellite is concerned, we used a compound galaxy model which consists of a spherical DM halo and a rotationally supported disk of gas and star (but no bulge) with independent parameters describing each of the structural component. The mass of the disk represents 5% of the total mass of the satellite and the gas mass fraction in the disk is fixed to a constant value 20% (of the total mass of the disk), consistent with observed values from the SDSS (Kannappan 2004). In all simulations, satellites are put on prograde or retrograde parabolic orbits (Khochfar & Burkert, 2006), with varying pericentric distance  $r_p$  and initial separations of  $r_{ini} = 100$  kpc.

The simulations are performed using the publicly available code GADGET2 (Springel 2005) with added prescriptions for cooling, star formation and feedback from Type Ia and II supernovae (SN). It is worth mentioning that gas particles with  $T < 2 \times 10^4 K$ , number

density  $n > 0.1 \text{ cm}^{-3}$ , overdensity  $\Delta\rho_{gas} > 100$  and  $\nabla \cdot v < 0$  form stars according to the standard star formation prescription:  $d\rho_*/dt = c_*\rho_{gas}/t_{dyn}$ , where  $\rho_*$  refers to the stellar density,  $t_{dyn}$  is the local dynamical timescale of the gas and  $c_*$  is the star formation efficiency.

In the present study, we use 10 times more particles than in K09 in order to more accurately study the evolution of the spatial distribution of stars. Consequently,  $\sim 4,000,000$  particles are used for each experiment in which the particle mass are  $M_{DM} = 3.03 \times 10^5 M_\odot$ ,  $M_{gas} = M_{disk} = 4.5 \times 10^4 M_\odot$  and  $M_E = 1.35 \times 10^5 M_\odot$  for the dark matter particles (DM), gas particles, star particles in the disk and star particles in the elliptical galaxy (E) respectively. The gravitational softening lengths ( $\epsilon$ ) used in each simulation are (*physical*)  $\epsilon_{DM} = \epsilon_E = 0.1 \text{ kpc}$  and  $\epsilon_{gas} = \epsilon_{disk} = 0.2 \text{ kpc}$ . We have also checked that increasing the resolution of the simulations as respect to K09 does not affect the star formation history for any given experiment which suggests that the conclusions presented in this work are robust. For instance, an example (experiment  $B_2$ ) is exhibited in Fig. 3 of K09.

We have considered several realizations whose relevant free parameters (e.g. initial orbital configuration and star formation efficiency) are summarized in Table 1. Our investigation mainly focuses on minor satellite mergers ( $1/10 \leq \text{mass ratio} \leq 1/4$ ) but we have also considered one major merger case (run  $D_1$ ) with which to compare the results.

## 2.2 WFC3 synthetic images modelling

This section describes the numerical modelling that enables the rendering of physically realistic telescope views with user-definable filter curves for a simulated instrument. The rendering process is done using ray tracing

**Figure 1.** Flow diagram describing the pipeline for the rendering of telescope views of the objects in the simulation

of light emitted by the simulated objects. For such purpose, we have developed and used the Alice code<sup>‡</sup>.

The instrument view render pipeline is described in Fig. 1. Firstly, the star and gas particles are projected onto a 2D array corresponding to the instrument’s charge-couple device (CCD) pixels (A). This is done using a cosmological distance ladder, assuming a  $\Lambda$ CDM cosmology (e.g. Hogg, 1999), with  $H = 70 \text{ km s}^{-1} \text{ Mpc}^{-1}$ ,  $\Omega_m = 0.3$  and  $\Omega_\Lambda = 0.7$  and a flat universe ( $k = 0$ ). Next, we assign a stellar energy distribution (SED) and emission line strength for various emission lines to each star particle (B), following Bruzual & Charlot (2003). To do this, we use an empirically-determined age-metallicity relationship, derived from Prochaska et al. (2003). The spectra are frequency-shifted according to the Hubble and peculiar velocity relative to the simulated observer. Then the code runs the emission from the star particles and then the absorption from the gas particles. Each of a given pixel’s spectra and emission line strengths are summed, and attenuated (C) according to the gas column density (Calzetti et al. 2000, 2001). It is worth mentioning that the resolution of the simulations is not enough to resolve dense molecular gas or dust. Therefore this may underestimate the total absorption which could affect the predicted UV emission. However, we don’t think the dust attenuation is very high since we showed in K09 that the (integrated) UV colours from this set of simulations reproduces the observed UV colours of the early-type galaxy populations extremely well. If we were systematically underestimating the dust content then we would probably see quite a big mismatch between the UV red envelope predicted by the model simulations and the observed one. In the next step, these spectra are passed

through a set of transmission filters (**D**). To do this, we linearly interpolate the spectra calculated with the given transmission curves. Finally, we produce flux maps corresponding to each transmission filter and emission line (**E**). We scale the fluxes to the minimum flux detectable by the instrument in each wavelength.

For the purposes of this work, the instrument parameters were taken from the WFC3 instrument. For instance, we have considered 5 filters: 2 from the near-infrared (NIR) field, J (F110W) and H(F160W), and 3 from the UV/optical field, NUV(F225W), the narrow-band  $H_{\beta}$  (F487N) and V (F555W) (see tables 2 and 3 for the associated wavelength bands). The UV colours are particularly suitable to detect young stellar populations inside interacting galaxies (see for instance, Hibbard et al. 2005) and remains largely unaffected by the age-metallicity degeneracy (Worthey 1994) while NIR spectral window traces primarily the old stellar populations.

Synthetic 2D images have been produced assuming luminosity distances of  $D = 100$  Mpc and  $D = 20$  Mpc corresponding to  $z \sim 0.023$  and  $z \sim 0.005$  respectively and according the cosmological parameters considered. An exposure time,  $t = 3600$  s was used for each of the broadband filters, while  $t = 7200$  s was used for the narrow-band  $H_{\beta}$  filter. We have assumed that each image is made up of 10 exposures in order to calculate an appropriate readout noise. The Field of View (FOV) of our synthetic images match those of the WFC3 detectors, namely:  $162 \times 162$  arcsec for UVIS images and  $133 \times 133$  arcsec for IR images. All the images have been convolved with an appropriate HST Point-Spread Function (PSF), derived using the *TinyTim*<sup>§</sup> software package (Krist & Hook 2004). Finally, an appropriate sky background, Poisson noise and readout noise have been added to each of the filtered images. Although generated at the full resolution of the UVIS instrument ( $4096 \times 4096$  pixels), the UVIS images presented in this paper have been re-binned to a resolution of  $1024 \times 1024$ .

## 3 RESULTS

### 3.1 Evolution of the star formation rates

In Figs. 2 and 3, we present the time evolution of the star formation rates (SFRs) derived from experiments described in the previous section. In each case, we have let the system evolve until  $t = 4.0$  Gyr from the beginning of the simulation, which corresponds to  $\sim 30 t_{dyn}$  where  $t_{dyn} = (r_{vir}^3/GM_{host}(r_{vir}))^{1/2}$  is the dynamical timescale at the virial radius of the host elliptical galaxy. In our models,  $r_{vir} \approx 13.5$  kpc and  $M_{host}(r_{vir}) \approx 3.12 \times 10^{10} M_{\odot}$  which lead to  $t_{dyn} \sim 1.3 \times 10^8$  yr. This value is consistent with observationally determined dynamical times from SDSS parameters (petroRad, photometric stellar masses, etc...) that are around 0.1 Gyr for ETGs. Young (2002) has also studied interferometric images of CO emission in five elliptical galaxies and derived some dynamical timescales for gas disks which are between 0.07 and 0.2 Gyr.

We first note the presence of peaks in the evolution of the SFRs that are associated with recent pericentric passages of the satellite. Indeed, at these specific times, an important fraction of available gas is consumed in starbursts due to the increase of the gas density during the interaction. The last peak in the SFRs is due to the final plunge of the satellite remnant. This behavior can be clearly seen in Fig. 2, where the evolution of the star formation rate derived from experiment  $B_2$  is plotted in parallel with the variation of the radial distance  $D$  of the bound part of the satellite remnant (with respect to the host galaxy center). We can observe that each SFR peak is preceded by a minimum in  $D$ . Physically these features arise due to tidal forces that induce instabilities in the satellite disk, resulting in loss of angular momentum via dynamical friction and infall to the centre.

The presence of several peaks in the SFR evolution seems to be a general trend in the case of minor merger events (mass ratio  $\leq 1:4$ ). A similar evolution is obtained even while assuming different star formation efficiencies or different initial orbital configurations (see Fig. 2). We also find similar behaviour for experiments  $B_5$  and  $B_6$  (e.g. for mass ratio 1:6 and  $r_p = 4$  and 2 kpc respectively). For reasons of clarity, we have omitted showing their evolution in Fig. 2.

However, the result is different for a major merger event. The right panel of Fig. 3 indicates that only 2 peaks are observed. In fact, the timescale of the merging process decreases as the mass ratio of the system increases. The time delays between the final plunge and the first peak are  $\sim 1.75$ ,  $\sim 1.25$  and  $\sim 1$ . Gyr for progenitor mass ratios of 1:10, 1:6 and 1:4 respectively. This is mainly due to the fact that the satellite galaxy gradually loses its energy and angular momentum under the action of dynamical friction, and finally sinks to the center of the host galaxy. This dynamical friction operates more slowly for minor merger events (see, for instance, Binney & Tremaine 2008). The ages of the individual mini-bursts are determined by the orbit and its dynamical evolution.

We also note that if the star formation efficiency  $c_*$  is low, a larger reservoir of gas remains at the time of the final plunge. This can sustain star formation in

**Figure 2.** The variations of the star formation rates derived from 1:6 merger mass ratio scenarios. The left panel shows the SFRs evolution for a fixed pericentric distance ( $r_p = 8$  kpc) but with different star formation efficiencies  $c_*$  values. The middle panel presents SFRs derived from experiments  $B_8$  (retrograde orbit) and  $B_7$  (edge-on parabolic merger). In the right panel, we have plotted in parallel the SFR derived from experiment  $B_2$  and the evolution of the radial distance of the most bound part of the satellite.

**Figure 3.** The variations of the star formation rates derived from 1:10 (left panel), 1:4 (middle panel) and 1:1 merger mass ratio scenarios.

the remnant for a longer time as is clearly suggested in Fig. 2. This result confirms both earlier studies (Larson 1974) and previous work based on merger simulations which show that gas can settle in a self-gravitating central disk which may feed a central black hole (Mihos & Hernquist, 1996 ; Barnes, 2002).

To finish, it should be pointed out that any initial transient starbursts and numerous fluctuations seen in the star formation rates before the first pericentric distance may result from non-equilibrium initial conditions. Indeed, such starbursts can happen at the beginning of the simulation since all stars are unaffected by feedback and then, most of them may be eligible to form stars. The numerous fluctuations seen in SFRs are also explained by the fact that a short period is needed for type II supernovae to be effective in order to regulate the star formation in the galaxy.

### 3.2 Evolution of the spatial distribution of stars

In this section, we focus on the evolution of the spatial distribution of stars. In our models, stars can be divided into 3 distinct groups: those that initially belong to the elliptical galaxy ( $E_*$ ), those that were present in the disk before the merger ( $D_*$ ), and finally the new stars which have formed during the merger process ( $N_*$ ). We are particularly interested in the latter stars. It is worth mentioning that we use the same initial age distribution as in K09, i.e, we assume that the elliptical is composed of old stars of age 9 Gyr whereas the mean age of the stellar population in the initial disk is 5 Gyr. The motivation of such choices are described in K09.

Fig. 4 shows the evolution of the projected distribution (face-on) of all stars in the experiment  $B_2$ . After 1.5 Gyr, we notice that the remnant satellite progressively forms a so-called “shell galaxy”, in agreement with previous numerical studies (Quinn 1984; Dupraz

**Figure 4.** The evolution of the projected spatial distribution of stars (face-on) from experiment  $B_2$ . Lines 1 and 2 show all stars in grey scale. In the upper panels, the dash blue lines indicate the trajectories of the satellite while the red arrows shows the initial spin of the spiral galaxy. Line 3 and 4 represent the stellar ages of the newly formed stars (in Gyr) at the same specific times. Each square is  $100 \times 100$  kpc in size.

& Combes 1986; Hernquist & Quinn 1988; Hernquist & Spiegel 1992; Hernquist & Mihos 1995). The age of all stars is also plotted with a colour coding. At large radius, the shell structure is mainly composed of a fossil stellar population of accreted stars  $D_*$ . Such trends are in good agreement with observations of massive ETGs (see for instance Clemens et al. 2009b). This is mainly due to the dissipationless process and angular momentum conservation during the merger. The newly formed stars  $N_*$  are generally formed in the central part of the satellite remnant where the density is higher. On the

contrary, the gaseous component of the satellite falls dissipatively into the potential well of the host galaxy and, after the final plunge, fuels rapid star formation. This latter phase is clearly active in the inner part of the system ( $\leq 3$  kpc), and after 2 Gyr it may be possible to measure a gradient in the age of the newly formed stars within  $\sim 40$  kpc, as suggested by Fig. 5. Since these new stars may have a higher metallicity than the host old ones, the presence of a metallicity gradient is also expected, in agreement with observations (Clemens et al. 2009b).

**Figure 5.** Evolution of the distribution of ages of newly formed stars (face-on) at different times from the beginning of the simulation for experiment  $B_2$ .

### 3.3 Size-Evolution of wet merger remnants

Simple arguments based on the virial theorem allow us to calculate the size evolution of the collisionless component of the merger remnant (e.g. Bezanon et al. 2009; Naab et al. 2009). Assuming the individual stellar components of the galaxies are in virial equilibrium:

$$E_i = -\frac{f}{2} \frac{GM_i^2}{r_i} \quad (1)$$

The factor  $f$  depends on the individual functional form of the profile and is close to  $f = 0.5$  in the case of de Vaucouleurs and exponential profiles. The radius  $r$  is the half-mass radius of the galaxy and  $M$  its stellar mass. The merging galaxies are set up to be on parabolic orbits with  $E_{orb} = 0$ , which allows us to write down the internal energy of the remnant assuming energy conservation as

$$E_{rem} = E_1 + E_2 + E_{orb} = -\frac{f}{2} G \left[ \frac{M_1^2}{r_1} + \frac{M_2^2}{r_2} \right]. \quad (2)$$

Assuming the remnant will settle down in virial equilibrium, then basic manipulations of Eq. 2 lead to

$$\frac{(M_1 + M_2)^2}{r_{rem}} = \frac{M_1^2}{r_1} + \frac{M_2^2}{r_2}. \quad (3)$$

In the following, we investigate the merger remnants and characterize the deviations from this simple virial argument based on the rate of dissipation and star formation occurring during the merger. For this purpose, we focus again on experiment  $B_2$  which can be considered as a typical minor merger scenario. In this case, we obtain  $r_{rem} \sim 5.67$  kpc.

From the simulation, the half-mass radius  $R_e$  at a given time is defined to be the radius of the circle containing half of the projected stellar mass. We have also studied the evolution of effective radius  $R_e^V$ , and  $R_e^H$

from V and H bands respectively.  $R_e^V$  and  $R_e^H$  are defined to be the radius containing half of the projected flux in each specific band. In order to take into account the effects of viewing angle, we have considered 100 different lines of sight chosen randomly and derived the mean value of  $R_e$ ,  $R_e^V$  and  $R_e^H$ .

Fig. 6 shows the evolution of  $R_e$ ,  $R_e^V$ , and  $R_e^H$  after the final plunge for experiment  $B_2$ . The evolution of  $R_e$  tends to a constant value ( $R_e \sim 5.05$  kpc) which is lower than the predicted value  $r_{rem} \sim 5.67$  kpc. This result is in agreement with the study of Covington et al. (2007) who show that the model systematically over-predicts the radii of remnants and using a wide range of merger simulations which account for dissipative energy losses and star formation.

The evolution of  $R_e^V$  is different and presents two phases. Firstly, a rapid decrease just after the final plunge ( $t \sim 1.6$  Gyr) which continues for  $\sim 0.5$  Gyr. This period corresponds to a phase of high star formation induced by the final plunge as shown in Fig. 2. The newly formed stars, mainly located in the central region, have a significant contribution of the total flux in the V-band leading to the reduction in  $R_e^V$ . In the second phase, beginning at  $t \sim 2.25$  Gyr,  $R_e^V$  increases due to the fact that the stellar population becomes progressively older. Indeed, such behavior can be clearly seen in the lower panel of Fig. 6 where we have plotted the evolution of the half-mass radius for each stellar component  $E_*$ ,  $D_*$  and  $N_*$ . The half-mass radius of the host elliptical galaxy tends to a constant value ( $\sim 4.2$  kpc) which is actually very close but lower than the initial value (4.29 kpc) and probably due to the adiabatic contraction induced by the infall of the satellite at the center. The half-mass radius of stars of the initial disk  $D_*$  also tends to a constant value ( $\sim 11.5$  kpc), which is quite high but explained again by the dissipationless process and angular momentum conservation during the merger. Finally, the half-mass radius for the newly formed stars  $N_*$  is rapidly decreasing until  $t \sim 3.0$  Gyr due to the high star formation induced after the final plunge. After this time, the increase observed in the evolution of  $R_e^V$  results from the ageing of the stellar population  $N_*$ .

The evolution of  $R_e^H$  follows the same trend, though the decrease after the final plunge is less pronounced but continues for a longer time ( $\sim 2.0$  Gyr). The value of  $R_e^H$  is close to  $R_e$  values but still smaller. It is expected that both  $R_e^V$  and  $R_e^H$  asymptotically tend to the value of  $R_e$  at late time. We infer that because of even modest amounts of star formation, the half-mass radius differs significantly from the half-light radius especially in the V-band. The observed half-light radius is expected to be smaller than the half-mass radius.

### 3.4 Evolution of WFC3 bands

In order to produce synthetic images, we have assumed our galaxy system to be in the local universe. Such a choice is motivated by the fact that up to two-thirds of nearby ETGs contains shells and ripples (see for instance Malin & Carter 1983; van Dokkum 2005) and these fine structures and disturbed morphologies often coincide with signatures of recent star formation (e.g.

**Figure 6.** The upper panel shows the evolution of the half-mass radius (green line) and effective radius from V (blue) and H (red) bands for experiment  $B_2$ . In the lower panel, we show the evolution of the half-mass radius for each stellar component: stars that initially belong to the host elliptical galaxy ( $E_*$ , red line), those that were present in the disk before the merger ( $D_*$ , green line) and the new stars which have been formed during the merger process ( $N_*$ , blue line). In each panel, the horizontal dashed line is the predicted half-mass radius value after the merger from arguments based on the virial theorem whereas the vertical dashed line is the epoch of the final plunge.

Schweizer et al. 1990; Schweizer & Seitzer 1992). It is then particularly interesting to try to characterize this spatially resolved fine structure whose detection is possible only in our local neighbourhood. For instance, using N-body simulations, Feldmann, Mayer & Carollo (2008) have shown that this broad tidal features cannot be reproduced by equal-mass dissipationless merger but is well explained by the accretion of disk-dominated galax-

ies. Moreover, minor mergers are expected to be more common than major mergers at low redshifts (Khochfar & Silk 2006; Genel et al. 2008; Khochfar & Silk 2009) and such statements support our choice of merger mass ratio values.

We start our investigation with experiment  $B_2$ . The galaxy pair is supposed to be at a redshift  $z \sim 0.023$  (or equivalently at a luminosity distance of  $D = 100$  Mpc) in order to facilitate comparisons with future observational data. In the following, the magnitude units given as measures of spectral flux are  $W.m^{-2}$ , and in all synthetic images, we use a logarithmic scale.

In Fig. 7, we present the grid map derived by our numerical modelling through the J and H bands. It appears that it is possible to resolve the host elliptical galaxy and the satellite remnant, in particular the shell structure which is mainly composed of old stars. However, this latter tends to disappear at  $t = 4.0$  Gyr. We also note that there are no significant differences between J and H bands. Fig. 8 shows the evolution of derived synthetic images from NUV,  $H_\beta$  and V bands. The ongoing star formation regions can be clearly followed through the three filters. In particular, after the final plunge, ongoing star formation located at the center of the galaxy can be clearly observed. In fact, when comparing with Fig. 4, only stars with ages  $\leq 0.5$  Gyr can be identified. Thus, the combination of IR and UVIS images allows us to separate different stellar populations and then distinguish the most bound part of the satellite remnant, composed of young stars, from the host galaxy, composed of older stars. This combination also gives useful clues on the formation of ETGs: while the shell structure revealed in IR images support a past merger scenario, evidence or not of the presence of young stars in UVIS images bring additional constraints on the wetness/dryness of the merger.

The same study has been performed for objects assumed to be at  $z \sim 0.005$  ( $D = 20$  Mpc). In this case, only the inner part is imaged due to the instrument FOV, as shown in Figs 9 and 10. The evidence of recent star formation is again clearly visible especially in the NUV band after the final plunge ( $t \geq 1.5$  Gyr). Some structures can also be distinguished around the central part and represent signatures of a recent merger event.

We have also studied how the free parameters (star formation efficiency and initial mass ratio) affect our results. For instance, Fig. 11 shows the evolution of synthetic images from the J and NUV bands in the experiment  $B_1$ . In this case, although the star formation efficiency is lower, the satellite remnant can also be identified in the NUV band. In the J band, the shell structure is less pronounced.

Comparison with mass ratios 1:4 and 1:10 presents similar conclusions although the structures are better resolved in the case of the 1:4 mass ratio due to the higher star formation induced during the merger (see Fig. 12 and 13). For instance maximum values in the NUV band between 1:4 and 1:10 merger mass ratios differ by up to an order of magnitude while they are comparable in the H band. However, simulations with the 1:4 merger mass ratio should be regarded as a limiting case, since it is close to the major merger scenario.

**Figure 7.** The evolution of synthetic images from experiment  $B_2$  through J (first line) and H band (second line) assuming the observed system at  $z \sim 0.023$ . The images have been Gaussian smoothed with a sigma of 2 pixels.

**Figure 8.** The evolution of synthetic images from experiment  $B_2$  through NUV (first line),  $H_\beta$  (second line) and V (third line) band assuming the observed system at  $z \sim 0.023$ .

## 4 DISCUSSION

The formation of early-type galaxies remains a major unresolved problem in astrophysics, and in particular their star formation history is known to be more complex than that of a single population model. Studies of nearby galaxy populations can provide useful clues to resolving this problem, by setting tight constraints on the level of the most recent star formation activity. In the present paper, we have used idealized hydrodynamical

simulations, including a standard star formation prescription, to study the minor merger process between an elliptical and a spiral galaxy which is expected to be the dominant channel in terms of the morphology of the merging galaxies (Khochfar & Burkert 2003). There is now observational evidence that massive ETGs may have undergone not more than one major merger since  $z \sim 0.7$  (Bell et al. 2006; McIntosh et al. 2008). Such results are supported by theoretical evidence that massive halos ( $\geq 10^{11} M_\odot$ ) experience only one major merger be-

**Figure 9.** The evolution of synthetic images from experiment  $B_2$  through J (first line) and H band (second line) assuming the observed system at  $z \sim 0.005$ .

**Figure 10.** The evolution of synthetic images from experiment  $B_2$  through NUV (first line),  $H_\beta$  (second line) and V (third line) band assuming the observed system at  $z \sim 0.005$ .

tween  $z = 2$  and  $z = 0$ , while minor mergers are much more common (Khochfar & Silk 2006; Genel et al. 2008; Khochfar & Silk 2009). We use idealised simulations in this work for two main reasons. Firstly, it allows us to reach a high mass resolution ( $\sim 10^{4-5} M_\odot$ ) with reasonable computational costs compared to cosmological simulations. Secondly, it permits us to consider a wide range of free parameters (including star formation efficiencies and initial orbital parameters) and to study how the results change accordingly.

We have generated 15 experiments by considering different merger mass ratios, (1:10, 1:6, 1:4 and 1:1) and three star formation efficiencies ( $c_* = 0.01, 0.05$  and  $0.1$ ). We find that the satellite is progressively disrupted by tidal torques and the star formation induced by the merger process shows several peaks in its evolution, associated with the passage of the remnant at decreasing pericentric distances. The satellite remnant progressively forms a shell structure within the host galaxy, which is composed of old stars at large radii and is ex-

**Figure 11.** The evolution of synthetic images from experiment  $B_1$  (mass ratio 1:6 and  $c_*=0.01$ ) through J (first line) and NUV (second line) assuming the observed system at  $z \sim 0.023$ .

**Figure 12.** The evolution of synthetic images from experiment  $A_2$  (mass ratio 1:10 and  $c_*=0.05$ ) through J (first line) and NUV (second line) assuming the observed system at  $z \sim 0.023$ .

plained by the fact that the stellar accretion and ensuing relaxation occurs via dissipationless mechanisms. On the contrary, the center is dominated by the newly formed stars due to the infall of the gas to the centre in a dissipative process. A positive radial age gradient is clearly seen and remains constant in time. All of these results are consistent with the conclusions of observational studies of massive ETGs (see for instance, Clemens et al. 2009b).

These typical shell structures are of particular interest as a means of characterizing the last merger experienced by the host galaxy, i.e, the mass ratio, dryness or orbital configuration. For instance, recently Canalizo et al. (2007) have tried to set constraints on the age of the plausible merger responsible for shell structures observed in a quasar host galaxy from HST/ACS. By using N-body simulations, they found that the merger occurred a few hundred Myr to  $\sim 2$  Gyr ago when

matching the observed and simulated outermost shell and causal connection with the quasar activity. But the accurate estimation of the age of the merger proves to be a very hard task due to the high number of orbital parameters, even when combining dynamical and photometric properties of the galaxy. For instance, Di Matteo et al. (2009) investigated the evolution of star formation efficiency in galaxy interactions and mergers using numerical simulations and found that retrograde orbits or high pericentric distances favor the enhancement of the star formation. Such degeneracy may be difficult to deal with.

Our main result is to demonstrate that colour information provides an important additional constraint via the induced star formation that together with the associated morphology provides further and important insights into the merger parameters. In particular, future observations especially with the resolution and NUV

**Figure 13.** The evolution of synthetic images from experiment  $C_2$  (mass ratio 1:4 and  $c_*=0.05$ ) through J (first line) and NUV (second line) assuming the observed system at  $z \sim 0.023$ .

power of WFC3 will open new vistas on star formation histories of ETGs. We have derived realistic synthetic images through J, H, NUV,  $H_\beta$  and V filters that can be compared with future WFC3 observations. Comparison of synthetic maps in the NUV and J bands for different merger mass ratios and star formation efficiencies gives similar results: evidence of recent star formation can be clearly detected before and after the final plunge, especially in the NUV band.

Our study does not include AGN feedback. We will consider this in a future paper. Here we note that while such a mechanism is supposed to play an important role in the early phases of the spheroid star formation, its role in the late phase is still poorly known. As suggested by our results, the infall of the gas at the final plunge can settle in a self-gravitating central disk which may feed a central black hole. For instance, N-body simulations including feedback from black hole accretion indicate that the quasar activity is coincident with the coalescence of the nuclei and eliminates all star formation afterwards (Springel, Di Matteo & Hernquist 2005). This will probably lead to a reduction of the total flux in the UVIS bands.

In summary, minor mergers seem to play a fundamental role in the late phases of ETG evolution. Minor mergers may be the principal mechanism behind the large UV scatter and associated low-level recent star formation observed in ETGs in the nearby universe (Kaviraj et al. 2009). In general, we find composite populations contributing to the star formation rate which persists for 2-3 Gyr, corresponding to several orbital times. Minor mergers naturally lead to star formation that is extended over a much longer period than for the single population starburst. The limiting case of major mergers results in much shorter star formation time-scales. Size evolution is another natural consequence of the minor merger model. The considerable amount of dissipation and central star formation reduces the apparent half-light radius of the merger remnant compared to its half-mass radius (see Fig. 6), thus indicating that size

determinations based on rest-band magnitudes sensitive to star formation will clearly underestimate sizes by factors of 1.2-1.6 for a few Gyr after the merger. Taking our results at face value and considering that the frequency of gas-rich minor mergers is larger at earlier times, the size-evolution of elliptical galaxies from high to low redshift could be milder than assumed so far.

To conclude, the present work shows that minor mergers induce amounts of star formation in ETGs which can be measured through UV bands. WFC3 represents the best instrument to study these minor merger events because it has a matching UV and optical FOV and gives the resolution to see young substructures (which would not be possible with GALEX for instance). The previous ACS/HRC UV detectors had a tiny FOV so it was not possible to study a galaxy up to 1 effective radius because one would get the whole galaxy in the optical image and only a fraction of its core using the UV. With WFC3, it is now possible to map the entire galaxy in both the UV and optical making it possible for the first time to perform spatially resolved star formation histories in ETGs at low redshift using the UV. Moreover the ability to see the young substructures is important because it rules out UV flux from old sources such as horizontal branch stars (which would follow the optical light profile).
