ABSTRACT
We report the result of a search for Lyα emission from the host galaxies of the gamma-ray bursts (GRBs) 030226 (z = 1.986), 021004 (z = 2.335) and 020124 (z = 3.198). We find that the host galaxy of GRB 021004 is an extended (around 8 kpc) strong Lyα emitter with a restframe equivalent width (EW) of 68\(^{+12}_{-11}\)˚A, and a star-formation rate of 10\(^{1.6}_{-2.0}\)\,\,M\(_{\odot}\) yr\(^{-1}\). We do not detect the hosts of GRB 030226 and GRB 020124, but the upper limits on their Lyα fluxes do not rule out large restframe EWs. In the fields of GRB 021004 and GRB 030226 we find seven and five other galaxies, respectively, with excess emission in the narrow-band filter. These galaxies are candidate Ly α emitting galaxies in the environment of the host galaxies. We have also compiled a list of all z \(\geq\) 2 GRB hosts, and demonstrate that a scenario where they trace star formation in an unbiased way is compatible with current observational constraints. Fitting the z = 3 luminosity function (LF) under this assumption, results in a characteristic luminosity of \(R^* = 24.6\) and a faint end slope of \(\alpha = -1.55\), consistent with the LF measured for Lyman-break galaxies.

Key words: dust, extinction – galaxies: evolution – galaxies: formation – galaxies: high-redshift – gamma-rays: bursts.

1 INTRODUCTION
Lyα photons face a large probability of being absorbed by dust particles due to resonant scattering. Therefore, Lyα emitting galaxies are often considered to contain little or no dust and to have low metallicity (Charlot & Fall 1993). However, a number of local metal-poor galaxies with active star formation show little signs of Lyα emission (e.g. Mas-Hesse et al. 2003; Hayes et al. 2005). In addition, the luminous dusty SCUBA galaxies often display Lyα in emission (Chapman et al. 2003). This indicates that dust and metallicity are not the only factors affecting the escape of Lyα photons; kinematical and geometrical properties of the interstellar medium may also play a major part (e.g. Neufeld 1991; Giavalisco et al. 1996). Assuming, however, the validity of the Charlot & Fall (1993) relation between metallicity and Lyα emission (see their fig. 8), implies that Lyα imaging is a probe of the star-formation rate (SFR), dust content and metallicity.

It is now firmly established that long-duration gamma-ray bursts (GRBs) are associated with star formation (e.g. Christensen et al. 2004) and, at least some, with core-collapse supernovae (e.g. Hjorth et al. 2003b; Stanek et al. 2003; Malesani et al. 2004; Thomsen et al. 2004). Lyα observations of GRB host galaxies provide information about...
their SFR, dust content and metallicity, knowledge which is crucial for our understanding of GRBs, their progenitors and environment. Furthermore, metallicity is an important parameter in some progenitor models. A high metallicity produces a strong stellar wind, which in turn leads to mass loss and loss of angular momentum. In the collapsar model these circumstances make it extremely problematic to generate a GRB (MacFadyen & Woosley 1999, see also Petrovic et al. 2005); a preference for GRB hosts to be metal-poor is therefore an unambiguous prediction of the collapsar model (assuming that the progenitor and host follow the same metallicity distribution). Alternative progenitor models exist where there is no such low metallicity preference (e.g. Ouyed et al. 2005; F ryer & Heger 2005).

There is growing evidence that the majority of GRB host galaxies, at least at high-z, are Lyα emitters (Fynbo et al. 2003a). If we define a Lyα emitter as having a Lyα restframe equivalent width (EW) larger than 10 Å, all of the five possible detections are confirmed Lyα emitters: GRB 071214 at z = 3.42 (Kulkarni et al. 1998; Ahn 2000), GRB 000926 at z = 2.04 (Fynbo et al. 2002, hereafter F02), GRB 011211 at z = 2.14 (Fynbo et al. 2003a), GRB 021004 at z = 2.34 (Møller et al. 2002) and GRB 030323 at z = 3.37 (Vreeswijk et al. 2004). For the latter two bursts, the Lyα emission line was detected superimposed on the afterglow spectrum. In addition, there is an indication of a Lyα emission line in the centre of the Lyα absorption trough in the GRB 030429 (z = 2.66) afterglow spectrum, although at a low significance level (Jakobsson et al. 2004a). As the GRB 030429 host is faint (R > 26.3) it would imply a relatively high EW. 

In this paper we present a study of the host galaxies and environments of GRB 021004 (z = 2.335), GRB 030226 (z = 1.986) and GRB 020124 (z = 3.198). The properties of GRB 021004 and its afterglow have been discussed in, e.g. Holland et al. (2003), Nakar et al. (2003), Matheson et al. (2003) and Bersier et al. (2003). Its host is, like most previously studied GRB hosts, a very blue starburst galaxy (R ≈ 24.5) with no evidence for dust (Fynbo et al. 2005a), whereas in the case of GRB 030226 there is no evidence for an underlying host galaxy (R > 26.2; Klose et al. 2004. GRB 020124 occurred in a very faint (R > 29.5; Berger et al. 2002) gas-rich galaxy with evidence for GRB surroundings with low dust content (Hjorth et al. 2003a).

We adopt a cosmology where the Hubble constant is $H_0 = 70 \text{ km s}^{-1} \text{ Mpc}^{-1}$, $\Omega_m = 0.3$ and $\Omega_{\Lambda} = 0.7$. For these parameters, a redshift of (1.986, 2.335, 3.198) corresponds to a luminosity distance of (15.41, 18.77, 27.45) Gpc and a distance modulus of (45.9, 46.4, 47.2). One arcsecond is equivalent to (8.38, 8.18, 7.55) proper kiloparsecs, and the lookback time is (10.2, 10.7, 11.5) Gyr. 

### 2 OBSERVATIONS & DATA REDUCTION

The observations were carried out during one night (two nights were lost due to bad weather) in October 2003 (GRB 021004) and four nights in March 2004 (GRB 030226) at the 2.56-m Nordic Optical Telescope (NOT) on La Palma, using the MOSaic CAmera (MOSCA). The MOSCA detector consists of four $2048 \times 2048$ CCDs with a pixel scale of $0.217''$ ($2 \times 2$ binning). The field of GRB 021004

Table 1. Total exposure time (in hours) and seeing in the combined image for each filter. GRB 021004 was observed in B, while GRB 030226 was observed in U. Note that when comparing the exposure times, GRB 020124 was observed with an 8-m telescope. 

(GRB 030226) was imaged in three filters: the standard B (U) and R filters and a special narrow-band filter manufactured by Omega Optical. The narrow-band filters were tuned to Lyα at $z = 2.331$ ($\lambda_{cen} = 4050 \text{ Å}$) and $z = 1.986$ ($\lambda_{cen} = 3630 \text{ Å}$) and had a width of $\Delta \lambda = 60 \text{ Å}$ (corresponding to a redshift width of $\Delta z = 0.049$ for Lyα). GRB 021024 was observed during several nights in March and April 2003 with the Very Large Telescope in Chile, using the FOCal Reducer and low dispersive Spectrograph (FORS1). The FORS1 detector consists of a single $2048 \times 2048$ CCD with a pixel scale of $0.2''$. As this was a Category B service mode programme, our observations were not completed, resulting in a total of only 5.7h of narrow-band imaging. An existing narrow-band filter, OIII/6000+52 ($\lambda_{cen} = 5105 \text{ Å}$) with a width of $\Delta \lambda = 61 \text{ Å}$, was used. For all three fields, the observations were carried out more than a year from the onset of the burst. An optical afterglow (OA) contribution is therefore negligible.

The individual exposures were bias-subtracted and flatfield corrected using standard techniques. The individual reduced images were combined using a $\sigma$-clipping routine optimised for faint sources (see details in Møller & Warren 1993). The total integration times along with the seeing in the combined images are given in Table 1. Narrow-band flux calibration was performed using observations of the spectrophotometric standard stars BD+28, GD71 and Hz44. The broadband images were calibrated using the Henden (2002, 2003) secondary standards. The transformations given in Fukugita et al. (1995) were finally used to bring the observations onto the AB-system. Conditions were not photometric when the NOT data were obtained, resulting in the narrow-band zeropoints being affected by clouds. Hence, they had to be adjusted as detailed in Sect. 3.1. This effect has not been taken into account in the uncertainties quoted in the paper.

### 3 RESULTS

We have used the same methods for photometry and selection of Lyα emitting galaxy candidates as those described in F02. In the following we will use the acronym LEDOs for Lyα Emitting Galaxy-building Objects, introduced by Møller & Fynbo (2001).

$^1$ A total of 18 hr were granted to the programme (to observe the GRB 020124 host).
requiring that the colours of objects detected at fairly high $S/N > 5$ in the narrow-band image, in the fields of GRB021004 (top) and GRB030226 (bottom). The dashed box encloses an area where all the model galaxy spectra are located (see main text for details). As expected, most objects have colours consistent with being in this box. However, a number of objects, including the GRB021004 host, are located in the lower left part of the diagrams. The filled circles indicate LEGO candidates. The solid curve corresponds to objects having the same broadband colours, but various amounts of absorption (upper part) or emission (lower part) in the narrow-band filter.

### 3.1 GRB 021004

In the upper part of Fig. 1, the $n_{AB} - B_{AB}$ versus $n_{AB} - R_{AB}$ colour-colour diagram is plotted for the detected objects in the GRB021004 field. The colours have not been corrected for Galactic extinction; such a correction would be negligible for $n_{AB} - B_{AB}$ and only shift objects slightly to the left (thus not affecting the number of LEGOs detected). In order to constrain where objects with no special features in the narrow-band filter fall in the diagram, we have calculated colours based on the synthetic galaxy spectra without Ly$\alpha$ emission provided by Bruzual & Charlot (1993). We have used models with ages ranging from a few Myr to 15 Gyr, with $0 < z < 3$. The box in Fig. 1 indicates the area where these model galaxies are located.

As mentioned above the narrow-band zeropoints for the NOT data were affected by cirrus. They were adjusted by requiring that the colours of objects detected at fairly high signal-to-noise ratio $(S/N)$ would fall on the locus of the model galaxies. The resulting change in the narrow-band zeropoint was approximately 25%, with an uncertainty of approximately 5%.

LEGOS will fall in the lower left corner of the diagram, due to excess emission in the narrow-band filter. We select as LEGO candidates objects detected at more than 5$\sigma$ in the narrow-band image and with a colour $n_{AB} - B_{AB} < -0.7$. This corresponds to an observed EW of about 67 Å, or 20 Å in the restframe for Ly$\alpha$ at $z = 2.335$. We find seven candidates in the field, including the host galaxy. Images of these LEGOs are shown in the left part of Fig. 2 and their photometric properties based on the total magnitudes $(m_{AB,auto}$ from SExtractor (Bertin & Arnouts 1996) are given in Table 2. The Ly$\alpha$ line flux is calculated by dividing the flux in the narrow-band filter with $1 + \Delta m/\Delta W_{obs}$. We also derive the SFR for the LEGOs, assuming that a Ly$\alpha$ luminosity of $10^{42}$ erg s$^{-1}$ corresponds to a SFR of 1 $M_\odot$ yr$^{-1}$ (Kennicutt 1998; Cowie & Hu 1998). These SFRs should be considered as lower limits, since the estimates might be affected by extinction.

The host galaxy of GRB021004 is detected in all bands and is a Ly$\alpha$ emitter with a restframe EW of 68$^{+12}_{-11}$ Å. Deep HST/ACS images of the host have been reported by Fynbo et al. (2005c). These images show that the host is dominated by a single component with the fwhm extending over 0.12 or roughly 1 kpc at $z = 2.335$. In Fig. 3 the contours of the Ly$\alpha$ emission are overplotted on an HST/ACS/WFC image, obtained 239 days after the burst. The Ly$\alpha$ weighted centroid is located very close to (and is consistent with) the centre of the galaxy, where the GRB originated. The extent of the Ly$\alpha$ emission is much larger than that of the continuum emission (about 1" after correcting for the seeing). A similar difference between contin-

uum and Lyα emitting regions is seen both for other high-z Lyα emitters (e.g. Fynbo et al. 2003) and for local starburst galaxies (Hayes et al. 2003).

3.2 GRB 030226

The host galaxy of GRB 030226 is not detected in any of the bands. We can set an upper limit (5σ) of $n_{AB} \approx 25.8$, corresponding to an observed emission line flux of $2.4 \times 10^{-17} \text{erg s}^{-1} \text{cm}^{-2}$. We calculate the broadband limiting magnitudes (2σ) in a circular aperture with a radius equal to the seeing, resulting in $R_{AB} \approx 24.9$ and $U_{AB} \approx 26.2$. In Fig. 4 we show a $10'' \times 10''$ region containing the position of the afterglow from a weighted sum of the combined Lyα and $U$-band images. The weight is calculated as the variance of the background after scaling to the same flux level. We detect no significant emission from the host above an estimated 2σ limit of $U_{AB} \approx 26.5$.

In the lower part of Fig. 4 the $n_{AB}-U_{AB}$ versus $n_{AB}-R_{AB}$ colour-colour diagram is plotted for the detected objects in the GRB 030226 field. We have followed a similar procedure as in Sect. 3.1 to select the LEGOs, resulting in the detection of five candidates. Here the colour criteria is $n_{AB}-U_{AB} < -0.6$, corresponding to an observed EW of about 60 Å, or 20 Å in the restframe for Lyα at $z = 1.986$.

The LEGO images are shown in the right part of Fig. 4 and their photometric properties are given in Table 3.

3.3 GRB 020124

Lacking broadband observations for the GRB 020124 field, we are unable to identify LEGO candidates. The host galaxy is not detected above a limit of $1.5 \times 10^{-17} \text{erg s}^{-1} \text{cm}^{-2}$ (5σ) in the narrow-band image. Since the host is very faint (Berger et al. 2002), this non-detection does not exclude a large Lyα EW (see below). In Fig. 4 we show a $10'' \times 10''$ region centred on the position of the afterglow.

3.4 Foreground Interlopers

Low-redshift galaxies with other emission lines in the narrow-band filter can mimic the high-redshift Lyα candidates we are aiming at (e.g. Stern et al. 2004). For the GRB 021004 host, the redshift is known from spectroscopy (Møller et al. 2002). For the remaining LEGO candidates, other emission line sources than Lyα are possible. We can exclude foreground galaxies with [OII] $\lambda$3727 in the GRB 021004 narrow-band filter, since such objects would have to be at a very low redshift ($z = 0.09$) and hence be much brighter than our candidates. Other possible explanations are CIV at $z = 1.34$ (GRB 030226) and $z = 1.61$ (GRB 021004), and MgII at $z = 0.30$ (GRB 030226) and $z = 0.45$ (GRB 021004). The presence of strong CIV and MgII emission requires an underlying active galactic nucleus (AGN). We have carried out a similar calculation as in F02 to show that the probability, that the expected number of AGNs in our field of view fall in the aforementioned small volumes, is of the order of 1%. Therefore, significant MgII and CIV contamination due to AGNs is not expected.
Table 4. A list of all GRBs with z > 1.9 known to date (May 2005). The detection method indicates how Ly\alpha in emission was detected. The host magnitudes are given in the Cousins/Johnson photometric system and have been corrected for Galactic extinction (Schlegel et al. 1998). The restframe wavelength is obtained by dividing the observed wavelength by (1+z). References are given in order for: redshift, Ly\alpha EWrest and host magnitude. (1) Kuilari et al. 4 DISCUSSION

4.1 LEGOs

We compare the properties of the LEGO candidates in the fields of GRB021004 and GRB030226 to properties of z ≃ 2 galaxies found in other surveys. The survey parameters (including flux limits) of Kurk et al. (2000) and Pentiricci et al. (2000), who have detected and spectroscopically confirmed 15 LEGOs (including the radio galaxy) in the field around PKS1138–262 at z = 2.156, are similar to ours. Their inferred number of LEGOs per arcmin² per unit redshift is 7.8 ± 2.0. The corresponding number for the fields of GRB000301C and GRB000926 (F02) is 8.3 ± 2.0. In addition, Fynbo et al. (2003a) find ~4.5 LEGOs per arcmin² per unit redshift in the field of GRB011211.

We observe 12 LEGO candidates in two ~50 arcmin² fields with a filter spanning Δz = 0.049. This corresponds to ~2.5 LEGOs per arcmin² per unit redshift. We note that the MOSCA field of view is around 60 arcmin², but the combined effect of the relatively large chip gaps (~8") and image dithering resulted in a loss of approximately 10 arcmin². The LEGO mean density for the five GRB fields observed thus far is about 5.6, consistent with that found around PKS1138–262. Unfortunately, there are currently no similar (in redshift and depth) surveys for Ly\alpha emitters in blank fields. Thus, the number of LEGOs representing the mean density at z ≃ 2 is uncertain. But there is some evidence that GRB host galaxies do not reside in high galaxy density environments (Bornancini et al. 2004; Foley et al. in preparation).

4.2 Ly\alpha Emission from the GRB Hosts

This study confirms what is already known about GRB021004, namely that its host is a strong Ly\alpha emitter with a restframe EW of 68+11\,12 Å, consistent with the value of 69 ± 14 Å estimated by Fynbo et al. (2005b) from a ground-based spectrum. The lack of Ly\alpha emission from the hosts of GRB030226 and GRB02104 in our deep narrow-band images does not rule out large restframe EWs. Assuming a GRB020124 host magnitude of R_{AB} ≃ 29.5 (consistent with the deep limit from Berger et al. 2002), a restframe Ly\alpha EW of ~500 Å would have remained undetectable. The corresponding value for GRB030226, assuming a host magnitude of U_{AB} ≃ 26.5, is ~40 Å. Fainter host magnitudes would result in even higher restframe EW limits.

4.3 Are GRBs Biased Tracers of Star Formation?

All current evidence is consistent with the conjecture that the host galaxies of GRBs, at least at high redshifts (z ≥ 2), are Ly\alpha emitters. An explanation could be an OA selection bias against dusty hosts (e.g. Tani et al. 2004, and references therein). However, the fraction of truly dark bursts is perhaps as small as 10% (e.g. Fynbo et al. 2001, Berger et al. 2002, Lamb et al. 2004, Jakobsson et al. 2004b, 2005). This suggests that GRB-selected galaxies should not be biased against very dusty systems.

A low metallicity preference for GRB progenitors, at least at high-z, is a possible interpretation of our results (Fynbo et al. 2003a). In this case GRBs could be biased tracers of star formation (e.g. Le Floc’h 2003). It is therefore of interest to consider whether our results are consistent with the hypothesis that GRBs are unbiased tracers of star
formation between approximately $2 \lesssim z \lesssim 4$, where the majority of known high-$z$ GRBs are located, and where the peak of the star-formation activity is situated.

In order to test this hypothesis we have collected all high-$z$ ($z \gtrsim 2$) GRB host galaxies reported in the literature, together with their redshifts, Lyα reframe EW if available, host magnitudes and host magnitudes redshifted to $z = 3$, assuming a flat $F_\nu$ spectrum (Table 1). Assuming that GRBs trace UV luminosity we fit the $z = 3$ magnitudes to the 

$$
\text{Schechter} \left[1976\right] \text{luminosity function (LF), including the upper limits as described in Appendix A. We find a characteristic magnitude of } 24.6_{-3.7}^{+0.6} \text{mag and a faint end slope of } \alpha = -1.55_{-0.16}^{+0.24} \text{ (the 1σ contour is shown in Fig. 4). We compare this to the R-band LF, corresponding to the reframe UV LF, for Lyman-break galaxies (LBGs) at } z = 3. \text{ The LBG LF has a characteristic magnitude of } 24.54_{-0.14}^{+0.14} \text{mag and a faint end slope of } \alpha = -1.57_{-0.14}^{+0.14} \text{ (Adelberger & Steidel } 2000\text{). Hence, there is consistency between the properties of the GRB host and LBG LFs, implying that GRBs are consistent with tracing the UV luminosity. Only } \sim 33\% \text{ of the } R < 25.5 \text{ LBGs are Lyα emitters with a reframe EW larger than } 10 \text{ Å (Shapley et al. } 2003\text{), but if this fraction is higher at fainter magnitudes this could be consistent with the high fraction of Lyα emitters among GRB hosts.}

The next question is whether UV luminosity on average is proportional to the SFR. Locally, such a correlation has been established (Kennicutt } 1998\text{), but it is known that for some starburst galaxies, most of the UV emission is absorbed and re-radiated by dust (e.g. Chapman et al. } 2003\text{). However, Chary & Elbaz } 2001\text{) argue that the contribution to the total SFR density at } z = 3 \text{ from dust-enshrouded ultraluminous IR galaxies (ULIRGs) is most likely less than } 30\%. \text{ Therefore it is a good first approximation to assume that the UV luminosity, for the bulk of the star-forming galaxies, is proportional to the SFR at } z = 3. \text{ In conclusion, the available data do not exclude GRBs as star-formation tracers, but additional observations are clearly required to settle the issue.}

If the mass-metallicity relation for galaxies (Tremonti et al. } 2004\text{) was already in place at } z \gtrsim 2 \text{ (Møller et al. } 2004\text{, Ledoux et al. } 2005\text{), a natural interpretation of our Lyα results, is that GRB hosts predominantly dominate the integrated star-formation density at all epochs.}

5 SUMMARY

We have carried out a narrow-band Lyα imaging of three GRB host galaxies and their environments. The GRB 021004 host ($z = 2.335$) is a strong Lyα emitter with a reframe EW of $68_{-11}^{+12} \text{ Å}$. We no detect the hosts of GRB 030226 ($z = 1.986$) and GRB 020124 ($z = 3.198$) in Lyα; the $5\sigma$ upper limits are $2.4 \times 10^{-17} \text{ erg s}^{-1} \text{ cm}^{-2}$ and $1.5 \times 10^{-17} \text{ erg s}^{-1} \text{ cm}^{-2}$, respectively. We find a total of 12 LEGOs in the fields of GRB 021004 and GRB 030226.

We have also assembled a list of all GRB hosts at $z \gtrsim 2$ reported in the literature. The distribution of the host magnitudes is consistent with the LF of LBGs at $z = 3$. If the LBG reframe UV continuum is proportional to the SFR, this suggests that the hypothesis of GRBs as star-formation tracers is consistent with current observations. In addition, when applying the mass-metallicity relation (Tremonti et al. } 2004\text{), this would imply that low-mass galaxies dominate the integrated star-formation density at all epochs.

To clarify the situation we need a complete and unbiased sample of GRB host galaxies with measured redshifts in a well defined redshift range. This is necessary in order to exclude any remaining uncertainty on whether the current sample is biased against dusty host galaxies. The currently
operating Swift satellite (Gehrels et al. 2004) offers a unique possibility to secure such a sample. We also need an independent gauge of the SFR distribution function in the same well defined redshift range. One suitable redshift range is \( z < 0.2 \) where large redshift surveys, such as the Sloan Digital Sky Survey (SDSS, e.g. Abazajian et al. 2003) and the 2dF Galaxy Redshift Survey (2dFGRS, e.g. Colless et al. 2003), have provided an extensive census and where it is possible to firmly constrain the amount of obscured star formation. Another possible redshift range is \( 2 < z < 4 \), where a plenitude of starburst selection techniques are available, e.g. LBGs, Ly\( \alpha \) galaxies, sub-mm galaxies and distant red galaxies, and where the peak of the cosmic star-formation density appears to have been located.

ACKNOWLEDGMENTS

We thank Stephanie Courtay for an intense and enlightening discussion on (specific) star formation, and the anonymous referee for a careful reading and useful corrections. PJ, GB and EHG gratefully acknowledge support from a special grant from the Icelandic Research Council. JPUF acknowledges support from the Instrument Centre for Danish Astrophysics (IDA) and the Nordic Optical Telescope (NOT). JG acknowledges the support of a Ramón y Cajal Fellowship from the Spanish Ministry of Education and Science. The research of JG is supported by the Spanish Ministry of Science and Education through programmes ESP2002-04124-C03-01 and AYA2004-01515. This work was supported by the Danish Natural Science Research Council. The authors acknowledge benefits from collaboration within the EU FP5 Research Training Network “Gamma-Ray Bursts: An Enigma and a Tool”. We are also grateful to the Nordic Optical Telescope Scientific Association (NOTSA) and the Science Institute, University of Iceland for financial support.

APPENDIX A: MAXIMUM LIKELIHOOD ANALYSIS

The Schechter luminosity function (LF) is given by:
\[ \Phi(L) \, dL = \Phi^* \left( \frac{L}{L^*} \right)^{\alpha} \exp \left( \frac{-L}{L^*} \right) \, d \left( \frac{L}{L^*} \right), \]
where \( \Phi^* \) is a number per unit volume and \( L^* \) is a characteristic luminosity (with an equivalent characteristic magnitude) at which the LF exhibits a rapid change in the slope in the \( (\log \Phi, \log L) \)-plane. The dimensionless parameter \( \alpha \) gives the slope of the LF in the \( (\log \Phi, \log L) \)-plane when \( L \ll L^* \).

If the probability of a GRB occurring in a galaxy is proportional to its UV luminosity, then the probability to find a GRB in a galaxy with UV luminosity \( L \) is proportional to \( L \times \Phi(L) \). Normalising this probability density we find:
\[ p(\alpha, L^*; L) = \frac{L^{\alpha+1} \exp(-L/L^*)}{(L^*)^{\alpha+2} \Gamma(\alpha + 2)}, \]
where \( \Gamma \) is the gamma-function. In the discussion we use the LBG restframe UV LF and compare with the sample of \( z > 2 \) GRB hosts.

Given the observed sample, we use the following likelihood function \( (LH) \) for \( L^* \) and \( \alpha \):
\[ LH(\alpha, L^*) = \prod_{i=1}^{N} p(\alpha, L^*; L_i) \times \prod_{j=1}^{M} \int_{0}^{L_j} p(\alpha, L^*; L) \, dL, \]
where \( N = 7 \) is the number of GRB hosts with a detected luminosity \( (L_i) \) and \( M = 6 \) is the number of GRB hosts with a luminosity upper limit \( (L_j) \). The maximum likelihood corresponds to an observed \( R \)-band magnitude of 24.8 and a faint end slope of \( \alpha = -1.53 \) (Fig. 5). The 1\( \sigma \) error contour in the \( (R^*, \alpha) \)-plane is found from the condition:
\[ \log \frac{LH(\alpha, R^*)}{LH_{\max}} = -1/2. \]
