ABSTRACT

We observed the quasar PG1211+143 using the Cosmic Origins Spectrograph on the Hubble Space Telescope in April 2015 as part of a joint campaign with the Chandra X-ray Observatory and the Jansky Very Large Array. Our ultraviolet spectra cover the wavelength range 912–2100 Å. We find a broad absorption feature (≈ 1080 km s\(^{-1}\)) at an observed wavelength of 1240 Å. Interpreting this as H I Ly\(\alpha\), in the rest frame of PG1211+143 \((z = 0.0809)\), this corresponds to an outflow velocity of \(-16,980 \text{ km s}^{-1}\) (outflow redshift \(z_{\text{out}} \approx -0.0551\)), matching the moderate ionization X-ray absorption system detected in our Chandra observation and reported previously by Pounds et al. (2016). With a minimum H I column density of \(\log N_{\text{HI}} > 14.5\), and no absorption in other UV resonance lines, this Ly\(\alpha\) absorber is consistent with arising in the same ultra-fast outflow as the X-ray absorbing gas. The Ly\(\alpha\) feature is weak or absent in archival ultraviolet spectra of PG1211+143, strongly suggesting that this absorption is transient, and intrinsic to PG1211+143. Such a simultaneous detection in two independent wavebands for the first time gives strong confirmation of the reality of an ultra-fast outflow in an active galactic nucleus.

Keywords: galaxies: active — galaxies: individual (PG1211+143) — galaxies: nuclei — galaxies: Seyfert

1. INTRODUCTION

Fast, massive outflows from active galactic nuclei (AGN) may play a prominent role in the evolution of their host galaxies. These outflows may both heat and remove the interstellar medium (ISM) of the host galaxy, effectively stopping further star formation, and removing the fuel for further black hole growth (Silk & Rees 1998; King 2003; Ostriker et al. 2010; Soker 2010; Faucher-Giguère & Quataert 2012; Zubovas & Nayakshin 2014; Thompson et al. 2015). Outflows implied by the X-ray warm absorbers and blue-shifted UV absorption lines commonly seen in nearby AGN (Crenshaw et al. 2003) are often too weak to potentially influence their host galaxies (Crenshaw & Kraemer 2012). On the other hand, ultra-fast outflows (UFOs), typified by high column densities of highly ionized gas and primarily identified via Fe XXVII K\(\alpha\) absorption outflowing at velocities of \(>10,000 \text{ km s}^{-1}\) would have the mass and kinetic energy to make a substantial impact on the evolution of their hosts (Pounds et al. 2003; Tombesi et al. 2011; Tombesi & Cappi 2014). However, given the low statistical significance of these features and the fact that they are often based on the identification of only a single spectral feature, Vaughan & Uttley (2008) have questioned their reality. The large, comprehensive Warm Absorbers in X-rays (WAX) survey (Laha et al. 2014) found no significant statistical evidence for UFOs in the six sources they had in common with Tombesi et al. (2011). While not discussing the data per se, Gallo & Fabian (2013) argue for an alternative explanation based on blurred reflection rather than an outflowing wind.

The Quasi-Stellar Object (QSO) PG1211+143 \((z = 0.0809)\) plays a central role in the controversy over relativistic outflows because it presents tantalizing evidence for the presence of UFOs and both intermediate- and lower velocity flows typical of warm absorbers. Pounds et al. (2003, 2010) identified two UFOs: one at high velocity \(v_{\text{out}} \approx -0.14c\), but also a lower velocity UFO at \(v_{\text{out}} \approx -0.06c\). However, studying the same origin...
inal XMM observation of PG1211+143 as Pounds et al. (2003), Kaspi & Behar (2006) find no evidence for UFOs, but rather lower-velocity systems more typical of those seen in warm absorbers. Pounds & Reeves (2009) and Tombesi et al. (2011) find UFOs persistently present, but varying in strength over the course of several XMM observations spanning months to years, while a long, 300 ks NuSTAR observation of PG1211+143 also finds no evidence for UFOs (Zoghbi et al. 2015).

Prior UV spectra of PG1211+143 revealed the usual blue continuum and broad emission lines typical of a Type 1 AGN, but no absorption lines typical of the outflows seen in other AGN. All absorption lines in the spectrum (including ones at velocities near that of the $v_{\text{out}} \sim -0.06$ c X-ray absorber) were identified as intervening gas in the intergalactic medium (IGM) (Penton et al. 2003; Tumlinson et al. 2005; Danforth & Shull 2008; Tilton et al. 2012). Given the variety of results obtained on PG1211+143 and its prominence in the controversy over the reality of high-velocity outflows in AGN, we undertook a large joint campaign using the Chandra X-ray Observatory, the Hubble Space Telescope (HST), and the Karl G. Jansky Very Large Array (VLA) to search for both X-ray and ultraviolet outflowing absorption systems. We report on the HST UV results here. See Danehkar et al. (2017) for the Chandra HETGS X-ray results complementing this paper. As in Danehkar et al. (2017), in this paper we will use the following conventions for velocities and redshift:

- $z_{\text{rest}} = 0.0809$ defines the rest frame of PG1211+143.
- $z_{\text{obs}}$ is the observed redshift of a spectral feature in our reference frame.
- $z_{\text{out}}$ gives the redshift of an outflow in the rest frame of PG1211+143.
- $\lambda_{\text{obs}}$ is the observed wavelength of a spectral feature.
- $\lambda$ is the rest wavelength (vacuum) of a spectral feature.

The usual special relativistic relations are used for conversions among the various quantities:

$$z_{\text{obs}} = \left( \frac{\lambda_{\text{obs}}}{\lambda} \right) - 1,$$
$$z_{\text{out}} = \left( 1 + z_{\text{obs}} \right) / \left( 1 + z_{\text{rest}} \right) - 1,$$
$$v_{\text{out}} = c \left[ \left( 1 + z_{\text{out}} \right)^2 - 1 \right] / \left[ \left( 1 + z_{\text{out}} \right)^2 + 1 \right],$$
$$z_{\text{out}} = \sqrt{\left( 1 + v_{\text{out}} / c \right) / \left( 1 - v_{\text{out}} / c \right) - 1},$$

where $c$ is the speed of light.

2. **HST OBSERVATIONS**

In April 2015 we observed PG1211+143 using *Chandra* and *HST* in a coordinated set of visits. The *HST/COS*
observations used grating G140L with a central wavelength setting of 1280 to cover the entire 912–2000 Å wavelength range (Green et al. 2012). To fill in the gap in wavelength coverage between segments A and B of the COS detector, in our second visit we also used grating G130M with a central wavelength setting of 1327 Å. The observations were summarized in Table I. All observations were split into four exposures at different FP-POS positions to enable us to remove detector artifacts and flat-field features.

The individual exposures in our program were combined by grating with updated wavelength calibrations, flat-fields, and flux calibrations using the methods of Kriss et al. (2011) and De Rosa et al. (2015). To adjust the wavelength zero points of our spectra, for G130M, we cross-correlated our spectra with the archival STIS spectrum of PG1211+143 (Tumlinson et al. 2005). For G140L, we measured the wavelengths of low-ionization interstellar lines and molecular hydrogen features and compared them to the H I velocity of $v_{LSR} = -17$ km s$^{-1}$ (Wakker et al. 2011). No adjustment to the G140L wavelength was required.

Our HST observations showed PG1211+143 to be similar in appearance to archival HST and IUE observations as shown in Figure I. The continuum flux at 1350 Å (1465 Å observed) was $F_{\lambda} = 2.2 \times 10^{-14}$ erg cm$^{-2}$ s$^{-1}$ Å$^{-1}$, slightly below the historical median flux of $2.9 \times 10^{-14}$ erg cm$^{-2}$ s$^{-1}$ Å$^{-1}$. Despite the lower flux and our shorter observation time, the signal-to-noise ratio (S/N) of our observation ($\sim 29$ per resolution element for G130M at 1240 Å) significantly improved upon the prior 25-orbit STIS echelle spectrum. Since the goal of our observations was to look for evidence of outflowing gas in PG1211+143 as evidenced by blue-shifted absorption lines, we scrutinized our spec-

Figure 2. HST/COS G130M spectrum covering wavelengths in the blue wing of the Ly$\alpha$ emission line of PG1211+143. The lower horizontal axis is the observed wavelength in Angstroms. The upper horizontal axis gives wavelengths in the rest frame of PG1211+143 at $z = 0.0809$. The broad feature labeled “Ly$\alpha$ absorption” at an observed wavelength of 1240 Å is weak or absent in archival spectra. Emission lines of C III* $\lambda 1176$ and Ly$\alpha$ in PG1211+143 are labeled. All other narrow absorption lines arise in foreground interstellar or intergalactic gas.

Although weak, narrow interstellar and intergalactic absorption lines have been previously cataloged in this region (Penton et al. 2004; Tumlinson et al. 2005; Danforth & Shull 2008; Tilton et al. 2012), this broad dip centered at $\sim 1240$ Å was not readily visible in prior

**HST spectra.** To convince ourselves that this feature was intrinsic to PG1211+143, and not an artifact in COS, we examined the individual exposures in each FP-POS setting. The broad absorption feature appears in all four exposures. Furthermore, no similar feature is present in any of the white dwarf standard star spectra obtained monthly as part of the COS calibration monitoring program.

To conclusively associate this single spectral feature with Lyα absorption intrinsic to PG1211+143, we note: (1) If it were N V, one would expect to see Lyα at shorter wavelengths, and also C IV at longer wavelengths. No features are present at those expected wavelengths in our observations. (2) The velocity of this feature in the rest frame of PG1211+143 matches the velocity of the detected soft X-ray absorption (Danekar et al. 2017). (3) We also detect Lyβ as described later in this section.

To measure the strength of the Lyα absorption feature, we used speckit (Kriss 1994) in IRAF to model the surrounding continuum and line emission and the embedded ISM and IGM absorption lines. For the continuum we used a reddened power law of the form $f_{\lambda} = 3.78 \times 10^{-14}(\lambda/1000 \AA)^{-0.779}$ erg cm$^{-2}$ s$^{-1}$ Å$^{-1}$ with foreground Galactic extinction of $E(B-V) = 0.030$ (Schlafly & Finkbeiner 2011). We also included foreground damped Lyα absorption due to the ISM with a column density of $N_{H} = 2.588 \times 10^{20}$ cm$^{-2}$ (Wakker et al. 2011). The Lyα emission line of PG1211+143 was modeled using three Gaussian emission components. Their parameters are summarized in Table 2. For the narrow foreground ISM and IGM lines, we used individual Voigt profiles. Finally, for the broad intrinsic Lyα absorption, we modeled its profile using two blended Gaussians in negative flux in order to account for its asymmetric, uneven profile. Since the broad Lyα line is well resolved, we obtain a lower limit on the column density using the apparent optical depth method (Savage & Sembach 1991) by integrating over the normalized absorption profile. The measured properties of the broad Lyα absorber are summarized in Table 3. Here we give the properties of the individual components in our fit as well as the properties of the full blended trough.

Since the short wavelength segment of our G140L grating observations covers the Lyβ region of PG1211+143, we are also able to measure Lyβ absorption over the same velocity range as we see in Lyα. The spectrum in this observed wavelength range is more complex due to foreground Galactic ISM features and the lower resolution of the G140L grating. To aid in this analysis, we retrieved the archival FUSE observation of PG1211+143 reported by Tumlinson et al. (2005). We convolved this with the COS G140L line-spread function (Roman-Duval et al. 2013) and scaled the flux level to match our COS spectrum at 1060 Å. The comparison shown in the lower panel of Figure 3 reveals a deficiency in flux in our COS spectrum relative to FUSE precisely at the wavelengths expected for a Lyβ counterpart to the G130M Lyα absorption feature. We are not able to resolve the Lyβ absorption in the same detail as we can for Lyα, so we simply measure its integrated properties. If we use the scaled and convolved FUSE spectrum to normalize the COS spectrum and integrate this normalized spectrum over the velocity range $-1500$ to $+1500$ km s$^{-1}$, again using the apparent optical depth method of (Savage & Sembach 1991), we obtain an equivalent width (EW) of 0.91 ± 0.27 Å. This flux deficiency is significant at a confidence level of $> 0.998$ compared to the null hypothesis of no absorption. As shown in Table 3, the strength of the Lyβ absorption is comparable to that of Lyα, suggesting that both spectral features might be heavily saturated. This sets a lower limit on the H I column density of $N_{H} > 2.9 \times 10^{14}$ cm$^{-2}$. Given that the features are not black at the bottoms of the troughs, the H I absorption would then only partially cover the continuum source. To measure the these covering fractions cited in Table 3, we use the depth at the center of the absorption trough. We note that since the Lyβ feature appears to be narrower than Lyα, this may indicate that the absorber is stratified in its column density, being more optically thick at line center than at higher velocities.

We do not see absorption associated with other high-ionization lines in the COS spectrum. No troughs associated with O VI, N V, or C IV are visible in our spectra. Although there appear to be deficiencies in flux in the COS spectrum at the expected locations of the O VI doublet in the lower panel of Figure 3, these are not statistically significant at more than $2\sigma$ confidence. Table 4 gives upper limits at $2\sigma$ confidence to the equivalent widths and column densities of these features assuming they have profiles similar to the detected Lyα absorption.

The high saturation present in H I and this lack of associated high-ionization lines suggests that this absorbing gas is both very highly ionized and of high total column density.

Tumlinson et al. (2005) observed PG1211+143 using a very deep (45 ks) STIS echelle E140M observation in 2002. We examined this archival spectrum to see if there was any indication of Lyα absorption at the velocity of our COS detection. Figure 4 compares the prior STIS observation of PG1211+143 to our new COS observation. One can see a slight depression in the same region as the much more prominent absorption we have detected with COS. Although this depression is marginally significant (P > 0.96 for the null hypothesis of no absorption), it
is not an obvious feature one would have selected without knowing where to look in the spectrum. Its weakness (or even absence) in the prior STIS spectrum indicates that this H I absorption feature is variable in strength. The HST-Faint Object Spectrograph observation of PG1211+143 in 1991 also bolsters this case for variability. Here we can set an upper limit on the presence of a Lyα absorption feature at v_\text{out} = -16,980 km s^-1 comparable to the strength of that in the STIS spectrum.

Outflows at velocities of −3000 km s^-1 and −24,000 km s^-1 have also been reported in prior X-ray observations of PG1211+143 (Pounds et al. 2003; Kaspi & Bchir 2006). We have carefully examined our COS spectra in these velocity ranges. As shown in Table 4 we find no evidence for H I absorption at any velocity other than surrounding −16,980 km s^-1.

3. DISCUSSION

Our joint Chandra and HST observations of PG1211+143 clarify the confusing kinematics of at least one major outflow component in this important example of a UFO. The HST-COS detection of a broad Lyα absorption feature at an outflow velocity of −16,980 km s^-1 (0.0541c) matches the velocity of the high-ionization absorption component detected in the joint Chandra-HETGS spectrum at v_\text{out} = −17,300 km s^-1 (z_\text{out} = −0.0561c) (Danehkar et al. 2017). This absorber

A UV COUNTERPART TO AN ULTRA-FAST X-RAY OUTFLOW IN PG1211+143
may be the same as the $-0.066c$ component detected in the deeper XMM-Newton EPIC-pn observation of Pounds et al. (2010), but it has lower ionization, log $\xi = 2.81$ compared to log $\xi = 3.4$, and it is much lower in column density, $N_{\text{H}} = 3 \times 10^{21}$ cm$^{-2}$ compared to $2 \times 10^{23}$ cm$^{-2}$. Analysis of the RGS data from the 2014 XMM-Newton observations (Reeves et al. 2017) reveals that this absorber has two components at velocities of $-0.062 \pm 0.001c$ ($v_{\text{out}} = -18600 \pm 300$ km s$^{-1}$) and $-0.059 \pm 0.002c$ ($v_{\text{out}} = -17700 \pm 600$ km s$^{-1}$), the latter of which is compatible with our detected H I absorption.

The kinematics of the Chandra X-ray absorber detected by Danehkar et al. (2017) make it a good match to the HST-COS Lyα absorber reported in this paper. A crucial question, however, is whether the absorbing gas detected in our UV spectrum is identically the same gas seen in the Chandra spectrum with the exact same physical conditions. Fukumura et al. (2010) constructed a photoionization model of a magnetohydrodynamically accelerated UFO in which the high-ionization gas producing Fe XXV could have also associated UV absorption lines (C IV in particular). They find that producing detectable ionic concentrations of low-ionization species typical of UV spectra, e.g., C IV, in such high-ionization gas requires a fairly soft spectrum with a low X-ray to UV luminosity ratio. In their model, they require $\alpha_{\text{ox}} = 1.7$, which is characteristic of higher redshift, high-luminosity QSOs. In the $z = 3.912$ UFO source APM 08279+5255, which has $\alpha_{\text{ox}} = 1.7$, Hagino et al. (2017) successfully produce a model that includes both low-ionization UV absorption consistent with the broad UV absorption lines viewed in this object as well as lower-ionization X-ray absorption (compared to Fe XXV). In contrast, our Chandra+HST observations show that PG 1211+143 has a much higher X-ray to UV luminosity ratio, with an observed $\alpha_{\text{ox}} = 1.47$. Our best-fit photoionization model for the X-ray absorbing gas in Danehkar et al. (2017) predicts very low column densities for all commonly observed UV metal ions (C IV, N V, and O VI). These predicted column densities are given in the last column of Table 3 and they are far below the upper limits for these ions that we measure in our HST spectra.

Although the ionic concentrations of the UV metal ions are extremely low, the predicted column density of H I is much higher due to its high abundance. Our best-fit photoionization model (Danehkar et al. 2017) predicts a neutral hydrogen column of $8.8 \times 10^{13}$ cm$^{-2}$. This is lower than the lower limit derived from our Lyα measurement, $> 2.9 \times 10^{14}$ cm$^{-2}$, but this prediction hinges crucially on the shape of the ionizing spectrum in the Lyman continuum. Our assumed spectral energy distribution is weighted toward a high ionizing luminosity since it extrapolates both the UV continuum and the soft X-ray continuum to a meeting point in the extreme ultraviolet (Figure 4 in Danehkar et al. 2017). However, a softer SED with a break to a steeper power law at the Lyman limit that then extrapolates to the detected soft X-ray continuum has half the ionizing flux in the Lyman continuum. Spectra with such a break are common in composite quasar spectra (Zheng et al. 1997; Telfer et al. 2002) and in the spectra of individual objects (Shang et al. 2005). With such a softer SED, the predicted neutral hydrogen column is $3.2 \times 10^{14}$ cm$^{-2}$, which is compatible with our UV observation.

Alternatively, one could reconcile the lower predicted H I column density of the X-ray spectrum with the higher column density observed in Lyα if the X-ray absorber is associated with only a portion of the Lyα trough. As illustrated by our model in Fig. 3 and the parameters in Table 3 the red component of the Lyα blend has a lower column density, compatible with the X-ray absorber. Its line width (FWHM = $320 \pm 74$ km s$^{-1}$, $v_{\text{turb}} = 226 \pm 52$ km s$^{-1}$) is also a better match to the turbulent velocity inferred for the X-ray absorber, $v_{\text{turb}} = 91^{+59}_{-59}$ km s$^{-1}$.

Although the column densities of detected (H I and undetected UV species are quite compatible with both the X-ray and UV absorption arising in the same gas, the complexity of the UV line profile relative to the X-ray may indicate that there are physically separate zones commingled in the outflow. Hagino et al. (2017) suggest that the UV absorbing gas in APM 08279+5255 is due to higher-density clumps embedded in the X-ray UFO. This may be true in PG 1211+143, but one would need higher signal-to-noise ratio X-ray observations with better spectral resolution as well as higher signal-to-noise ratio UV observations of the Lyβ and O VI region to resolve this possibility.

A UV Counterpart to an Ultra-Fast X-ray Outflow in PG1211+143

central energy distribution in Danekar et al. (2017), the fractional abundance of H I scales with $\xi$ as log $N_{\text{HI}} = -3.47 - 1.4 \log \xi$. Thus this $\sim 0.129$ cgs component should have an associated neutral hydrogen column density of $\sim 3.1 \times 10^{14}$ cm$^{-2}$, which should be easily visible in a UV spectrum. Indeed, this is as strong as the Ly$\alpha$ absorption we detect that is associated with the lower velocity, lower ionization component of the outflow detected in our Chandra spectrum. At the location of a putative $-0.129c$ component in our COS spectrum, we can set an upper limit on any Ly$\alpha$ absorption of $< 1.0 \times 10^{13}$ cm$^{-2}$, well below any expected absorption associated with such a component. At log $\xi = 3.4$ or 4.0, the trace columns of other UV-absorbing ions such as O VI, N V, or C IV would be $N_{\text{ion}} < 10^{13}$ cm$^{-2}$ and undetectable in our COS spectra. Although we detect neither X-ray nor UV absorption associated with the high-velocity $-0.129c$ outflow, this could simply be due to variability, as even the H I counterpart of the $v_{\text{out}} = -17.300$ km s$^{-1}$ ($z_{\text{out}} = -0.0561$) X-ray absorber is not always detectable, as shown in Fig. 4.

While we do not confirm all of the ultrafast outflow components previously seen in PG1211+143, we do have a robust detection of one at an outflow velocity of $v_{\text{out}} = -16.980$ km s$^{-1}$ ($z_{\text{out}} = -0.0551$). However, this outflow component is considerably lower in total column density than previously suggested features. Is it then massive enough and energetic enough to have a substantive impact on the evolution of its host galaxy? As usual, this is still ambiguous since derivation of the mass outflow rate and the kinetic luminosity depend on the location of the absorbing gas we have detected. The further from the central source, the more massive the outflow, and the higher its kinetic luminosity. Assuming the outflow is in the form of a partial thin spherical shell moving with velocity $v$, its mass flux, $\dot{M}$, and kinetic luminosity, $L_k$, are given by:

$$\dot{M} = 4\pi \Delta \Omega R N_{\text{H I}} m_p v$$

$$L_k = \frac{1}{2} M v^2$$

where $\Delta \Omega$ is the fraction of the total solid angle occupied by the outflow, $R$ is the distance of the outflow from the central source, $N_{\text{H I}}$ is the total hydrogen column density of the outflow, $m_p$ is the mass of the proton, and $\mu = 1.15$ is the molecular weight of the plasma per proton. Since Tombesi et al. (2010) argues that roughly 50% of AGN have ultrafast, high-ionization outflows, we assume $\Delta \Omega = 0.5$.

As many authors have argued, the maximum radius can be estimated by assuming a plasma of uniform density distributed along the line of sight to the central source, so that $N_{\text{H I}} = n R$ (e.g., Blustin et al. 2003; Reeves & Pounds 2012; Ebro et al. 2013). Given that we know the ionization parameter $\xi = L_{\text{ion}}/(nR^2)$, this gives the constraint $R < L_{\text{ion}}/(N_{\text{H I}} \xi)$. For our observation of PG1211+143 and the SED presented by Danekar et al. (2017), $L_{\text{ion}} = 1.587 \times 10^{45}$ erg s$^{-1}$, $N_{\text{H I}} = 3 \times 10^{21}$ cm$^{-2}$ and $v = 16.980$ km s$^{-1}$, so that $R < 265$ pc, $M < 799$ M$_\odot$ yr$^{-1}$ and $L_k < 7.3 \times 10^{46}$ erg s$^{-1}$. Our SED for PG1211+143 gives a bolometric luminosity of $5.3 \times 10^{45}$ erg s$^{-1}$, so at this maximum distance the outflow would be depositing up to $14 \times$ the bolometric luminosity as mechanical energy into the host galaxy. This even exceeds the Eddington luminosity of $1.8 \times 10^{46}$ erg s$^{-1}$ for its black hole mass of $1.46 \times 10^8$ M$_\odot$ (Peterson et al. 2004). However, given the unrealistic assumption involved in this approximation (i.e., a single ionization parameter describes gas uniformly distributed from 0 to 265 pc), this merely demonstrates the potentially powerful influence of this outflow on the host galaxy.

At the other extreme, if we assume the gas is a thin spherical shell at the radius where its velocity equals the escape velocity of its central black hole, for $v = 16.980$ km s$^{-1}$, $R = 5$ lt-days, the impact is minimal, with a mass outflow rate of $> 0.013$ M$_\odot$ yr$^{-1}$, and a kinetic luminosity of $> 1.2 \times 10^{42}$ erg s$^{-1}$.

If the absorbing cloud is associated with an ejection event in 2001, we can set a better-motivated constraint on the location of the absorber. Variability in the Ly$\alpha$ absorption feature argues for changes related to motion of the absorber rather than an ionization response due to the magnitude of the variability. The observed changes in strength (from absence, or near-absence) from the prior FOS and STIS observations to our COS observation are much stronger than expected based on changes in the luminosity of PG1211+143. In the archival record, PG1211+143 spans a range in UV brightness at 1464 Å from $2.0 \times 10^{-14}$ erg cm$^{-2}$ s$^{-1}$ Å$^{-1}$ to $4.6 \times 10^{-14}$ erg cm$^{-2}$ s$^{-1}$ Å$^{-1}$ (Dunn et al. 2006). The FOS and STIS observations bracket this range with flux levels of $2.1 \times 10^{-14}$ erg cm$^{-2}$ s$^{-1}$ Å$^{-1}$ and $4.6 \times 10^{-14}$ erg cm$^{-2}$ s$^{-1}$ Å$^{-1}$, respectively.

Our COS observation lies near the lower end at $2.4 \times 10^{-14}$ erg cm$^{-2}$ s$^{-1}$ Å$^{-1}$. For our adopted SED (Figure 4 in Danekar et al. 2017), a factor of 2 change in flux translates to a factor of 2.5 change in the neutral hydrogen column density. Given the saturation present in Ly$\alpha$ in our COS spectrum, the column density has increased by more than a factor of 3.3. This bolsters the case that the X-ray/UV outflow is not continuous. It could either have originated as an ejection event around 2001, or it could imply that the absorbing cloud is moving transverse to our line of sight.

For motion at $-16.980$ km s$^{-1}$, an ejected cloud would have moved outward to a distance of $7 \times 10^{17}$ cm (0.23 pc) over 13 years. A thin spherical shell at this distance would imply a mass outflow rate of $> 0.013$ M$_\odot$ yr$^{-1}$, and a kinetic luminosity of $6 \times 10^{45}$ erg s$^{-1}$. It is interesting to observe that this is more similar to the minimum kinetic luminosity of $3 \times 10^{44}$ erg s$^{-1}$ we derived for a potential radio jet based on the VLA observations (Danehkar et al. 2017), which appears energetically similar to the X-ray/UV outflow.

Unfortunately, none of these estimates is definitive since we have no good measurement of the actual location and duration of the outflow. With so few spectral diagnostics, pinning down the radius of such an outflow would require intensive monitoring to measure recombination timescales in the photoionized gas.

4. SUMMARY

We have obtained high S/N UV spectra of the QSO PG1211+143 covering the 900–1800 Å bandpass si-
multaneously with a deep Chandra X-ray observation [Danechkar et al. 2017]. Our ultraviolet spectra detect a fast, broad Lyα absorption feature outflowing at a velocity of \(v_{\text{out}} = -16.980 \, \text{km s}^{-1} \) (\(z_{\text{out}} = -0.0551\)) with a FWHM of 1080 km s\(^{-1}\). A possible feature associated with Lyβ is also detected at 99.8% confidence, but no other ionic species are detected in absorption at this velocity. This H\(\text{i}\) absorption feature is a likely counterpart of the highly ionized warm absorber detected in our Chandra HETGS spectrum at an outflow velocity of \(v_{\text{out}} = -17.300 \, \text{km s}^{-1} \) (\(z_{\text{out}} = -0.0561\)). This ultrafast outflow may be the same as the \(v_{\text{out}} \sim -0.06\)c outflow reported in previous XMM-Newton observations by Pounds et al. (2016) and Reeves et al. (2017). Our detection of H\(\text{i}\) absorption associated with these outflows demonstrates that neutral hydrogen is a very sensitive tracer of high-column density gas even at high ionization.

Based on observations made with the NASA/ESA HST, and obtained from the Hubble Legacy Archive. This work was supported by NASA through a grant for HST program number 13947 from the Space Telescope Science Institute (STScI), which is operated by the Association of Universities for Research in Astronomy, Incorporated, under NASA contract NAS5-26555, and from the Chandra X-ray Observatory (CXC) via grant GO5-16108X. TF was partly supported by grant 11525312 from the National Science Foundation of China.
