### ABSTRACT:

Feedstocks from lignocellulosic biomass (LCB) include crop residues and dedicated perennial biomass crops, of which the latter are often considered superior in terms of climate change mitigation potential. Uncertainty remains over their availability as feedstocks for biomass provision and the net greenhouse gas emissions (GHG) during crop production. Our objective was to assess the optimal land allocation to wheat and Miscanthus in a specific case study located in England, in order to increase biomass availability, improve the carbon balance (and reduce the consequent GHG emissions), minimally constrain grain production losses from wheat. Using soil and climate variables for a catchment in East England, biomass yields and direct soil nitrogen emissions were simulated with validated process-based models. A ‘Field to up-stream factory gate’ Life Cycle Assessment was conducted to estimate indirect management-related GHG emissions. Results show that feedstock supply from wheat straw can be beneficially supplemented with LCB from Miscanthus grown on selected low quality soils. In our study, 8% of the less productive arable land area was dedicated to Miscanthus, increasing total LCB provision by about 150%, with a 52% reduction in GHG emission per ton LCB delivered and only a minor effect on wheat grain production (-3%). In conclusion, even without considering the likely carbon sequestration in impoverished soils, agriculture

1 should embrace the opportunities of providing the bioeconomy with LCB from dedicated,  
2 perennial crops.

## 8 1 INTRODUCTION

9 With the potential benefits in climate change mitigation, development of rural economy,  
10 energy security and reducing fossil fuel dependency, biomass crops have attracted interest  
11 in both bioenergy and biomaterial production. At present ‘first generation’ biomass (1GB)  
12 has been the major feedstock and technology deployed in national bio-economy strategies.  
13 However, concerns about competition for food, land use change, loss of biodiversity and  
14 raised GHG emissions<sup>1</sup> have led to an increased focus on the utilization of lignocellulosic  
15 biomass (LCB), resourced from agricultural and forestry residues and dedicated biomass  
16 crops.

17 The drivers for LCB feedstocks include mainly their higher Energy Return On  
18 Investment<sup>2</sup>, and better environmental and social performance than 1GB in the sustainability  
19 assessment. However, there are concerns regarding the actual provisioning capacity of LCB,  
20 especially from agricultural residues such as cereal straw. Although there have been many  
21 attempts to calculate this potential<sup>3-6</sup>, it remains difficult to quantify<sup>7</sup>. Most estimates of  
22 straw production are based on measurements of grain production and assuming a constant  
23 relationship between grain and straw yield<sup>5</sup>. Cereal straw production is concentrated in the  
24 arable eastern parts of England; around 70% of UK wheat straw is produced in the Yorkshire  
25 and Humber region, East Midlands, East Anglia and the Southeast regions<sup>6</sup>. In the UK, straw

1 is mainly used for animal bedding, horticulture and bioenergy<sup>8</sup>, with 32% to 39% being  
2 incorporated back to the soil to maintain the soil organic carbon (SOC) content<sup>4</sup>. Only  
3 approximate 300 to 487kt/year (2-4% of total produced cereal and oilseed rape straw) was  
4 used for bioenergy generation<sup>6</sup>. There are no robust official survey data available for straw  
5 usage in animal bedding; estimates range between 5.8 Mt and 6.24 Mt annually for all cereal  
6 and oilseed rape straw, based on livestock statistics from Defra (Department of  
7 Environment, Food and Rural Affairs)<sup>6,8</sup>. Current straw use is shown in Fig. 1 based on a  
8 wide range of literature<sup>4,6,8</sup>.

9 Dedicated biomass crops have the advantage that they can be grown on marginal arable  
10 land<sup>9,10</sup>. However, the actual land area needed to produce the specified amount of biomass  
11 could be higher due to lower and variable local productivity<sup>11</sup>. Currently, one of the main  
12 challenges for lignocellulosic bioenergy or biomaterial production is that the high overall  
13 production cost is dominated by pretreatment costs of LCB feedstock<sup>12</sup>. The overall  
14 production cost could be aggravated when the feedstock prices increase due to emerging  
15 competition for biomass across the sub-sectors of bio-economy (bioenergy, biomaterial and  
16 traditional uses, such as animal feed and bedding etc.)<sup>12,13,14</sup>.

17 Figure 1.

18 Most research on biogeochemical impacts of Miscanthus are conducted on silt clay loam  
19 soil<sup>15-19</sup>. However, it is less likely that those soils could be converted to Miscanthus  
20 production, due to farmers' unwillingness to change, especially on soils where they  
21 generally achieve good yields for conventional arable crops. Understanding the performance  
22 of Miscanthus on a wider range of soil types, especially on sandy soils which have low cereal  
23 yields but high nitrogen (N) losses<sup>20</sup> is important to identify the suitable locations for  
24 Miscanthus production. **Compared to wheat, higher yields of Miscanthus with lower N**

1 **inputs** and losses per unit of production are likely to reduce Greenhouse Gas (GHG)  
2 emissions of biomass production and lower **its environmental footprint** and costs.

3 Accurate estimates of GHG emissions and resource use efficiencies are important in  
4 understanding and determining the sustainability of bioenergy and bio-based chemicals. Full  
5 Life Cycle Assessment (LCA) for biorefinery chains are often constrained by the lack of  
6 sufficiently detailed and site-specific information on the pre-harvest GHG balance related to  
7 agricultural management, especially N<sub>2</sub>O emissions from N fertiliser application, as an  
8 important source of GHG<sup>21</sup>. The IPCC Tier 1 method provides a default estimate of N<sub>2</sub>O  
9 emissions from agriculture for both, direct and indirect emissions, based on N fertiliser  
10 inputs, but ignores other important crop management, soil and atmospheric variables. The  
11 Tier 3 approach suggests the use of process-based biogeochemical models to achieve more  
12 accurate site-specific estimates of the GHG flux from variable agricultural systems<sup>22</sup>. A  
13 number of studies have integrated process-based model generated N<sub>2</sub>O emission results into  
14 LCA<sup>21,23,24</sup>. However, most of this work has been carried out solely for conventional crops  
15 (first generation biomass)<sup>21,23</sup>. Very limited work can be found for simulating the pre-harvest  
16 N<sub>2</sub>O emission for perennial energy crops such as Miscanthus based on process-based  
17 models, due to the limited availability of such models developed for dedicated LCB crops  
18 integrated into arable cropping systems. To address this gap, process-based models  
19 STAMINA (Stability and Mitigation of Arable Systems in Hilly Landscapes)<sup>25</sup> and carbon-  
20 nitrogen (C, N) turnover model DNDC (i.e. DeNitrification-DeComposition)<sup>26</sup> were used  
21 for Tier 3 approaches to estimate dry matter yields (DMYs) and the N emissions of winter  
22 wheat and Miscanthus.

23 The overall objective of this paper is to estimate the impacts and benefits of moving from  
24 an ‘arable only’ to a proposed ‘mixed (arable and perennial)’ feedstock provision scenario.

1 We assessed the potential of local LCB provisioning capacity, and the resulting GHG  
2 emissions under different supply scenarios, whilst exploring the potential impacts arising  
3 from integrating Miscanthus into a wheat production system in eastern England.

## 4 2 MATERIAL AND METHODS

5 The crop growth model system STAMINA<sup>25</sup> and C-N turnover model DNDC<sup>26</sup> were  
6 calibrated to estimate DMY data only, considering both, winter wheat and Miscanthus. No  
7 model evaluation could be done for N<sub>2</sub>O emission and NO<sub>3</sub><sup>-</sup> leaching arising from their  
8 supply due to lack of experimental data. They were up-scaled to the catchment to estimate  
9 the LCB supply capacity and GHG balance of production in a rural area nearby the city of  
10 Hull in England (max. 50 km as feedstock transport distance from farm to conversion plant;  
11 Fig. 2). The catchment consists of parts of the Yorkshire & Humber and East Midlands  
12 regions, major wheat production areas in England.

13 Firstly, crop growth parameters for both, the STAMINA and DNDC models were  
14 calibrated based on literature and evaluated against observations on farms across England.  
15 Three indicators, including coefficient of determination (R<sup>2</sup>), root mean square error  
16 (RMSE) and relative mean absolute bias error expressed as a percentage (MBE%) were  
17 calculated to assess the goodness-of-fit between model simulated and measured yields of  
18 both crops. Secondly, LCB availability, NO<sub>3</sub><sup>-</sup> leaching and N<sub>2</sub>O emissions were simulated  
19 for both, 'arable only' and proposed 'mixed arable-perennial' feedstock supply scenarios.  
20 For the latter, Miscanthus was assumed to replace wheat on selected low-quality soils, which  
21 are coarse textured, less productive and have the highest NO<sub>3</sub><sup>-</sup> leaching/wheat grain  
22 production ratio (kgN/t Grain) based on modelled results. These represent 8% of the total  
23 catchment area. Thirdly, the GHG balance results were combined with a 'field to up-stream  
24 factory gate' LCA to compare the global warming potential (GWP) associated with different

1 lignocellulosic feedstock supply scenarios.

2 Figure 2

### 3 2.1 Process-based models

4 The STAMINA modelling system simulates micro-meteorology, hydrology, crop  
5 development and growth, integrating spatial information on soil and topography for a range  
6 of crops, including both arable crops (winter wheat, maize, potato, barley etc.) and perennial  
7 crops (Miscanthus, willow, switchgrass etc.). The STAMINA-winter wheat model is  
8 described in detail elsewhere<sup>27</sup>. In this work, the catchment region is represented as a matrix  
9 of 1km<sup>2</sup> cells, within which all important variables of soil, climate, crop and crop  
10 management are assumed to be homogeneous. STAMINA-winter wheat model had been  
11 calibrated against winter wheat yields observed in Bedfordshire (England)<sup>27</sup>. Here, three sets  
12 of UK weather, soil and on-farm measured yield data from an earlier study<sup>28</sup> (Table 1) were  
13 used for **model evaluation**. DMYs were simulated with an acceptable accuracy (Fig. 3),  
14 **RMSE of 1.36 t/ha and MBE% of 12%**. The STAMINA-BeGRAS Model is a sink-source  
15 interaction model based on the principles described in LINGRA for small grasses<sup>29</sup> and was  
16 expanded for the allocation of biomass to belowground biomass (rhizomes and roots).  
17 BeGRAS model was implemented in the STAMINA modelling system<sup>30</sup> and calibrated for  
18 Miscanthus using detailed data collected at Rothamsted Research. In this simulation work  
19 for Miscanthus, weather, soil and on-farm measured yield data (Table 1) from the  
20 Rothamsted 408 trial<sup>31</sup> are used for **model evaluation**. The RMSE between measured and  
21 simulated yields is 1.58 t/ha and MBE % is **12% (Fig. 3)**. **The BeGraS model simulated**  
22 **Miscanthus DMYs at harvest (1<sup>st</sup> to 3<sup>rd</sup> March) after two establishment years, for 13 years**  
23 **of harvest**. The RMSE between measured and simulated yields was 1.58 t/ha and MBE% is

1 12% (Fig. 3). 30-year average scenario yields (two 15-year growing cycles) were generated  
2 for each soil type to be used in the overall assessment.

3 DNDC model was originally designed to simulate C and N biogeochemical cycles  
4 occurring in agricultural systems at regional scales in the U.S.<sup>32</sup> and was further extended to  
5 cover a wider range of countries and districts and other ecosystems<sup>33,34</sup>. DNDC is capable  
6 of predicting the main GHGs fluxes from soil (N<sub>2</sub>O, CO<sub>2</sub> and CH<sub>4</sub>) and other key  
7 environmental and economic indicators, including crop yields, ammonia (NH<sub>3</sub>)  
8 volatilization and nitrate (NO<sub>3</sub><sup>-</sup>) leaching rates and quantities<sup>35,36</sup>. In DNDC, N<sub>2</sub>O emissions  
9 were determined based on denitrification and nitrification pathways as a function of climate,  
10 crop growth and soil environmental factors. DNDC was parameterized for winter wheat by  
11 using published values<sup>37</sup> and site specific data. Comparison between modelled and measured  
12 yields is shown in Fig. 4. Modelled yields compare quite well with observations, considering  
13 the average values (8.64 and 8.65 t/ha respectively) and statistics (RMSE of 1.02 t/ha and  
14 MBE% of 12%). Miscanthus parameters in the DNDC model had been parameterized using  
15 literature data and tested earlier<sup>18</sup> calibrated and validated using observed yields over four  
16 years at a site in Urbana, Illinois, USA. To use the model under UK condition, we  
17 recalibrated the parameters using measured Miscanthus DMYS from 1997 to 2004 in the  
18 Rothamsted 408 trial<sup>31</sup>, soil parameters for a clay loam (Batcombe series) and locally  
19 recorded weather data. The simulated and observed DMYS are displayed in Fig. 4, with  
20 RMSE of 1.57t/ha, and MBE % of 11%.

1 Figure 4.

2 Figure 5.

3 Table 2.

#### 4 2.2 Inputs for feedstock scenario simulations

5 The catchment used for the scenario simulation covers an area of 5,856 km<sup>2</sup> and  
6 comprised 48 soil series according to UK National Soil Map (1 km grid) (NATMAP vector,  
7 Cranfield University, 2001), which can be grouped in to nine soil texture classes (Fig. 5).  
8 The input data source and the target modelling outputs were listed in Table 2. Key soil  
9 information includes soil texture, SOC, bulk density, pH, soil available water capacity  
10 (AWC) within rooting depth. STAMINA modelling framework requires information on air  
11 temperature, precipitation, wind speed, solar radiation and atmospheric humidity. In this  
12 work, three climate scenarios were examined, i.e. baseline, medium and high CO<sub>2</sub> emissions.  
13 Hourly data collected from High Mowthorpe weather station from 1961-1990 were used for  
14 baseline simulation, assuming an atmospheric CO<sub>2</sub> concentration of 352 mg litre<sup>-1</sup>. Weather  
15 data were generated for the medium and high emissions scenarios using UK Climate  
16 Projections (UKCP09)<sup>38,39</sup>. In the UKCP 09, CO<sub>2</sub> emissions under the three IPCC SRES  
17 scenarios A1FI, A1B1 and B1 are used and labelled High, Medium and Low according to  
18 how different emissions pathways affect future climate. We used the projected CO<sub>2</sub>  
19 concentrations for 2030 of 447 mg litre<sup>-1</sup> for the Medium (A1B) and 449mg litre<sup>-1</sup> for the  
20 High (A1F1) Scenario as average CO<sub>2</sub> concentrations for 2020-2050 timeframe<sup>40</sup>.

21 In the DNDC modelling, we applied an approach similar to that of Guo<sup>21</sup> who simulated  
22 N and C dynamics using 5 years' of weather data (1986 to 1990) and an atmospheric CO<sub>2</sub>  
23 concentration of 360 mg litre<sup>-1</sup>. In addition to the weather data, DNDC also requires N

1 concentration in the rainfall, atmospheric NH<sub>3</sub> concentration and fertiliser application  
2 information. Rainfall N concentration were derived from the UK Eutrophying and  
3 Acidifying Pollutant Network (UKEAP). The calculated 5 years mean rainfall NH<sub>4</sub><sup>+</sup>-N and  
4 NO<sub>3</sub><sup>-</sup>-N concentration at Thorganby station of 1.27mg litre<sup>-1</sup> was applied in this study.  
5 Atmospheric NH<sub>3</sub> 5-year average concentration obtained from UKEAP-National Ammonia  
6 Monitoring Network (Easingwold station) of 2.54 µgN/m<sup>3</sup> was applied in this study. N  
7 fertiliser type is assumed to be ammonium nitrate. For winter wheat, the annual input values  
8 range from 160kgN/ha to 220kgN/ha, depending on the soil series. This was calculated using  
9 DEFRA's fertiliser manual (RB209) for each soil series, based on the information including  
10 soil texture, soil total N level, precipitation, previous crop types and any particular crop  
11 quality (feed or backing) requirements<sup>41</sup>. For Miscanthus, 60kgN/ha/year of ammonium  
12 nitrate was assumed in the simulation.

13 For crop production management, the single feedstock production scenario (SP) assumes  
14 winter wheat is grown on all the arable land across the whole catchment area (Table 3). The  
15 mixed feedstock production scenario (MP) assumes that winter wheat is still the  
16 predominating crop, while Miscanthus was cultivated only on selected low quality soils (8%  
17 of total area), balancing N<sub>2</sub>O emissions, NO<sub>3</sub><sup>-</sup> losses, wheat grain production and LCB  
18 feedstock provision.

19 Table 3.

20 Straw availability was estimated based on the wheat grain production level, wheat planted  
21 area, wheat grain harvest index, harvestable straw fraction, incorporation rate and  
22 competition in demand of other uses. Due to the limited availability of data on current straw  
23 production and use, we adopted a conservative estimation of winter wheat straw provision  
24 potential for the case study area. Wheat grain harvest index (HI) is simulated by the

1 STAMINA-winter wheat model, resulting in a 30-year average value of 0.53 in these study  
 2 scenarios. We assume that 50% of all the leaves and stems produced over the entire wheat  
 3 growing season have been lost through decay by the time of harvest. The remaining 50% of  
 4 the residual biomass is harvested in the first two years, however, in the third year it is left  
 5 on the ground to maintain SOC content. The total harvestable straw tonnage is calculated  
 6 with Equation 1, where  $x$  is the modelled grain yield (in t/ha, 14.5% moisture) and 265,600  
 7 ha was estimated based on the assumption that due to rotation, 2/3 of the total 398,400 ha  
 8 arable land is used for winter wheat cultivation:

$$9 \quad \text{Total straw harvested (tonnes)} = \left(\frac{x}{0.53} - x\right) * 0.5 * \left(1 - \frac{1}{3}\right) * 265600 \quad (1)$$

### 10 2.3 Life cycle assessment (LCA)

11 Field to upstream factory gate LCAs were conducted for both single SPBC and MPBC  
 12 scenarios. The LCA covers the emissions per unit of delivered lignocellulosic feedstock,  
 13 which includes the cultivation, preparation for transport, transport to storage and transport  
 14 to processing plant in defined case study locations (Fig. 6.). Within the cultivation phase the  
 15 emissions are considered from upstream production of materials and raw material extraction,  
 16 fuel inputs required for on-farm cultivation, as well as direct and indirect N<sub>2</sub>O emissions.  
 17 Indirect N<sub>2</sub>O emissions due to NO<sub>3</sub><sup>-</sup> leaching were estimated based on modelled NO<sub>3</sub><sup>-</sup>  
 18 leaching values and IPCC default emission factor EF5<sup>42</sup>.

19 Table 4.

20 Figure 6.

21

22 LCA inputs for wheat and Miscanthus cultivation are shown in Table 4. For wheat straw,  
 23 general agricultural data for operations on the field (including machinery use and associated

1 diesel consumption) is taken from the BEAT database which derives its data from the Farm  
2 Management Pocketbook<sup>43</sup>. The cultivation processes include ploughing, harrowing,  
3 fertiliser application, top dress, pesticide application, combine harvesting, and straw baling  
4 and carting. As defined by the BEAT database, the wheat straw is naturally dried in storage  
5 with no additional inputs apart from its offloading and loading from the storage location.  
6 Transport is assumed to be bulk freight road transport using >32t gross weight vehicles as  
7 defined in the Ecoinvent database<sup>44</sup>. Diesel consumption for loading and offloading of  
8 feedstocks is calculated basing on the movement of 15t/hour feedstock with the consumption  
9 of 493 MJ/hour diesel<sup>45</sup>. To maintain consistency with the DNDC simulations, same  
10 amounts of ammonium nitrate input levels were adopted in LCA and DNDC simulations.  
11 The remaining cultivation data for Miscanthus (including subsoiling, ploughing, harrowing,  
12 fertiliser application, spraying, weed cultivation and residue removal) has been compiled  
13 from the Sustainable Liquid Biofuels from Biomass Biorefining (SUNLIBB) project  
14 database<sup>46</sup>, which has been developed for Europe primarily from UK data. **Transport is**  
15 **assumed to be same as above for wheat straw.** Upstream data for the production of the inputs  
16 specified in the feedstock cultivation input trees is taken from Ecoinvent v3.1<sup>44</sup>. The  
17 combustion of diesel in agricultural equipment for various tasks (e.g. fertiliser application,  
18 harvesting, baling etc.) is taken from IPCC<sup>22</sup> and Kubica et al.<sup>47</sup>. The environmental impacts  
19 associated with this data is calculated in Simapro 8 using the ReCiPe Midpoint (H) LCA  
20 impact assessment methodology.

21 **As cultivation data count for the whole wheat crop, the impacts of cultivation need to be**  
22 **allocated to wheat grain or straw. Three allocation methods were applied in this work, i.e.**  
23 **economic allocation, RED\_allocation and CV\_allocation. Economic data for wheat straw**  
24 **and grain taken from Statistics Denmark show prices of €0.074 and €0.15/kg, respectively,**  
25 **assuming provision of the public good ‘straw for energy’<sup>48</sup>. According to Renewable Energy**

1 Directive (EU RED)<sup>49</sup>, straw shall be considered to have zero life-cycle GHG emissions up  
2 to the process of collection of those materials. Additionally, we allocated emissions based  
3 on the real calorific values (CV) of wheat grain and straw, which are 16.5 and 17.6 MJ/kg,  
4 respectively<sup>50</sup>.

### 5 3 RESULTS

#### 6 3.1 Single feedstock production scenarios

7 Modelled 30-year average grain yields for all the soil series range from 7.20 to 8.33 t/ha  
8 (14.5% moisture), depending on variable soil AWC. Weighted average yield was calculated  
9 basing on the proportion of each soil series in total area. The overall weighted average yield  
10 in the region is 7.94 t/ha (14.5% moisture). Yields were also simulated for medium and high  
11 emission climate change scenarios (Table 4). Like in the baseline results, soils of high AWC  
12 can achieve slightly higher yields. The overall weighted average yields are 8.54 and 8.76  
13 t/ha for medium and high emission scenarios respectively. Total amount of harvestable  
14 wheat straw are estimated to be 623, 670 and 688 kt/year for the chosen catchment area  
15 under baseline, medium and high emission scenarios, respectively (Table 5). About 97% of  
16 the current wheat straw currently has other uses<sup>4,6,8</sup> (Fig. 1), which is 604kt per year. Under  
17 the medium and high emission scenario, assuming the annual demands from other uses will  
18 remain stable, then a total amount of 66 and 83 kt wheat straw could become available for  
19 bioenergy or biomaterial production.

20 Table 5.

21 Figure 7.

22 Simulated NO<sub>3</sub><sup>-</sup> leaching and winter wheat grain yields of different soil textures show a  
23 high variation in NO<sub>3</sub><sup>-</sup> leaching and gas flux from different soil textures (Fig. 7) in the DNDC  
24 outputs. NO<sub>3</sub><sup>-</sup> leaching is the main sink for N loss; depending on soil texture, the 4-year

1 average  $\text{NO}_3^-$  leached ranges between 14 and 135 kgN/ha/year. The annual leaching fractions  
2 ( $\text{NO}_3^-$  leached per N fertiliser inputs) for different soil textures range from 6 to 60% of total  
3 applied N. The weighted average leaching amount is 63.3 kg N/ha which corresponds to a  
4 leaching fraction of 30%.

5 These results are similar to the IPCC Tier 1 estimate for FracLEACH-(H) (N losses by  
6 leaching/runoff for regions), according to which the rate of N loss by leaching or run off is  
7 30% of the total N fertiliser input, with an uncertainty range of 10 to 80%<sup>22</sup>. This result is  
8 also in accordance with the winter wheat long-term field trial 'Broadbalk Experiment'  
9 conducted in England, where 21% and 31% N loss were observed for the 192 and 240kgN/ha  
10 N fertiliser application treatments, respectively<sup>51</sup>.

### 11 3.2 Mixed feedstock production scenarios

12 In the mixed feedstock production (MP) scenarios, Miscanthus was assumed to be  
13 planted on all those soils with loamy fine sand texture. For those soils, simulated winter  
14 wheat yields are much lower than on the other soils while the N leaching is substantially  
15 higher than finer textured soils (Fig. 7). On these soils, the Miscanthus produces about 12-  
16 13t/ha, compared to only 1.5 to 2.0 t/ha of winter wheat straw becoming available. The  
17 comparison of modelled  $\text{NO}_3^-$  leaching and  $\text{N}_2\text{O}$  emissions between wheat straw and  
18 Miscanthus on those four loamy fine sand soils are shown in Fig. 8. Similar to winter wheat  
19 production, model outputs also show a positive effect of increasing  $\text{CO}_2$  concentration on  
20 Miscanthus production (Table 6). Compared with the SP scenario, total available LCB  
21 increases from 19 kt (SPBC) to 384 kt (MPBC) under the baseline climate. Under the  
22 medium and higher climate change scenarios, the differences increase from 365 to 504 kt  
23 and 545 kt total available LCB production, respectively (Fig. 9).

24 Figure 8.

1 Figure 9.

2 About 11% of  $\text{NO}_3^-$  leaching could be prevented when MPBC feedstock scenarios were  
3 adopted (Table 7), equating to a saving of approximately 2.81 million kg N/year. A  
4 relatively minor reduction (6.06%) in direct  $\text{N}_2\text{O}$  emissions is estimated by DNDC  
5 (0.66kgN/ha for SPBC and 0.62kgN/ha for MPBC). In total, 34,925 kg N/year (10,408 t  
6  $\text{CO}_2\text{eq/year}$ )  $\text{N}_2\text{O}$  emission could be saved moving from SPBC to MPBC feedstocks.

7 Table 7.

### 8 3.3 LCA results

9 The direct and indirect  $\text{N}_2\text{O}$  emission results were included in the field to upstream  
10 factory gate LCA for both SPBC and MPBC scenarios (Fig. 10). When economic allocation  
11 was applied, the LCA shows an impact of 0.20 kg  $\text{CO}_2\text{eq/kg}$  delivered LCB for SPBC  
12 scenario, and this figure decreases for 52% in MPBC system. A similar trend can be found  
13 when CV allocation was used. However if RED allocation was considered, the GWP for  
14 SPBC is only 0.020 kg  $\text{CO}_2\text{eq/kg}$  and increases to 0.087 kg  $\text{CO}_2\text{eq/kg}$  when MPBC was  
15 adopted. This is due to that RED allocation approach requires all the emissions of wheat  
16 cultivation to be attributed to grain production. It can also be noted that cultivation phrase  
17 contributes to the biggest portion of GWP (from 77% to 94%) in all the scenarios except SP  
18 when RED allocation is used. Furthermore,  $\text{N}_2\text{O}$  emission accounts for 14% to 16% of total  
19 emissions except for SPBC scenario under RED allocation.

22 4 DISCUSSION

1 In this study, the process based models DNDC and STAMINA, were calibrated and  
2 evaluated for winter wheat and Miscanthus under local English conditions. Both models  
3 simulated yields quite well when compared to observed yields for both crops. DNDC has  
4 been widely used for simulating C and N dynamics for a range of crops. However, as  
5 Miscanthus was not included in the original version of the model, only two articles have  
6 been published using DNDC to simulate Miscanthus growth before<sup>18,52</sup>. In the work reported  
7 here, we tested the DNDC model's performance in simulating Miscanthus yields under local  
8 conditions, however, uncertainty remains on the model's ability to accurately simulate N  
9 dynamics, for which it was not possible to calibrate the model in this work.

10 Due to the lack of information on current straw production and use, a conservative  
11 estimate of winter wheat straw provision potential was adopted. It has been suggested that  
12 straw which was used for animal bedding could be used locally for soil incorporation after  
13 (serving as farmyard manure), allowing substantial reduction of the incorporated straw and  
14 making more straw available for bio-energy or bio-material production. However, this is less  
15 likely to happen considering current records from Copeland and Turley<sup>6</sup> according to which  
16 a large volume of straw is moved from the Eastern Counties to the South West of England,  
17 Wales and Scotland to meet the market demands for animal bedding in the livestock sector<sup>7</sup>,  
18 rather than being used locally.

19 Medium and high CO<sub>2</sub> emission climate change scenarios were used to model production  
20 of winter wheat and Miscanthus, however, as both STAMINA and UKCP only examine the  
21 impacts of altered atmospheric factors (CO<sub>2</sub> concentration, rainfall, temperature etc.) on crop  
22 growth, they do not include issues such as altered occurrence of pest and diseases, which are  
23 likely to impact on yields. Based on simulations of projected CO<sub>2</sub> concentration and  
24 corresponding weather information from the UKCP, no negative impacts on wheat and

1 Miscanthus yields have been seen. On the contrary, our simulations predict increases of  
2 7.6% and 10.3% for wheat grain yields under medium and high scenarios respectively, and  
3 33.9% and 43.2% increase of Miscanthus yields compared with the baseline climate.  
4 Simulated increases in wheat productivity were in accordance with most of the current  
5 research in that C3 crops show yield increases in response to rising CO<sub>2</sub> concentration  
6 through increased rates of photosynthesis and decreased water use<sup>53</sup>. Unlike C3 crops, the  
7 impacts of elevated CO<sub>2</sub> concentration on C4 crops growth remains uncertain<sup>53</sup>. In theory,  
8 the increase of biomass from elevated atmospheric CO<sub>2</sub> concentration on C4 crops should  
9 be very limited or even none, however this has been shown only in some of the research  
10 conducted<sup>53</sup>, whilst others have seen substantial increases in photosynthesis and biomass  
11 production at increased CO<sub>2</sub> concentrations<sup>54,55</sup>. Apart from the elevated CO<sub>2</sub> concentration,  
12 our simulated increases in Miscanthus yields under climate change scenarios could be  
13 explained by the much warmer climate (48.71% and 46.67% higher average hourly  
14 temperatures), higher average humidity (13.91% and 14.21% higher humidity) and slightly  
15 higher annual precipitation levels (2.51% and 2.56% higher annual rainfall) projected by  
16 UKCP compared with the baseline climate. It has been widely discussed that Miscanthus  
17 growth in Northern Europe is mainly constrained from reaching its potential by the cold  
18 temperature<sup>11,56</sup>.

19 Comparing our estimated total available LCB for single and mixed feedstock production  
20 under different climate change scenarios, it is clear that the proposed MP scenarios benefit  
21 significantly more than the SP scenarios. Under the SP scenarios, it is impossible to ensure  
22 sufficient feedstock for a new development of an exclusively locally supplied lignocellulosic  
23 biofuel or biomaterial plant in the case study area, even for the SPHE scenario, when the  
24 available LCB is estimated to be 82kt/year. However, if the 8% selected area with low  
25 quality soils were to be converted to Miscanthus cultivation, available LCB supply is

1 estimated to be 383kt/year for **MPBC** and 628kt/year for **MPHE**, which is sufficient to  
2 support one to two commercial scale lignocellulosic biofuel or biomaterial plants, with 3%  
3 reduction in regional wheat grain supply.

4 The simulated and estimated  $\text{NO}_3^-$  leaching and  $\text{N}_2\text{O}$  emissions of both SPBC and MPBC  
5 scenarios indicated that if Miscanthus is integrated into the arable system by replacing  
6 conventional cereal crops on low-quality soils (where wheat production levels are lower and  
7 N losses higher), weighted average  $\text{NO}_3^-$  leaching across the whole feedstock supply region  
8 would be reduced by 10% and the total of direct and indirect  $\text{N}_2\text{O}$  emissions would be  
9 reduced by 8%. The reduction of GWP from SPBC to MPBC scenario becomes larger  
10 according to the LCA results, due to the reduced fertiliser application, machinery use and  
11 associated energy consumption.

12 **When calculating GWP from agricultural residues, the choice of allocation method is**  
13 **crucial in deciding the LCA results. In this work, when RED allocation is used, the results**  
14 **were completely in contrary to those using economic allocation and CV allocation. It**  
15 **suggests that the current allocation method in RED is too simplified to reflect the real GHG**  
16 **dynamics reliably, especially when comparison with perennial crops is made.**

17 Assessing the C stock impacts arising from the change in land use from wheat to  
18 Miscanthus was outside the scope of this work. However, a few studies have shown C stock  
19 increases for arable land converted to Miscanthus, in both above ground biomass and below  
20 ground C pool<sup>57-60</sup>. **Our recent analyses show that soil carbon enrichment under Miscanthus**  
21 **can be marginal on soils rich in carbon<sup>9</sup> but considerable in low quality soils<sup>61</sup>.** Thus, we  
22 would expect to see a further reduction of GWP by moving from SPBC to MPBC as C stocks  
23 would increase from land use change to perennial crops. GWP arising from land use change  
24 will be assessed in an additional paper.

1

2           5           CONCLUSION

3           GWP of the non-food bioeconomy can be improved considerably (5-6%) when LCB  
4           resourcing is changed from a SPBC to a MPBC system. Integrating Miscanthus on sandy  
5           soils into the UK arable system improves the feedstock availability omitting low yield and  
6           high N loss locations for wheat production. In such an MP scenario, total available LCB  
7           increases by more than an order of magnitude **with limited impact on** wheat production.  
8           Simulated  $\text{NO}_3^-$  leaching and  $\text{N}_2\text{O}$  emissions from Miscanthus production are 50% to 60%  
9           lower than from wheat on these low-quality soils, showing a win-win situation regarding  
10          environmental and economic criteria.

11          This work **clearly** challenges two preconceptions that have emerged **for** the non-food  
12          bioeconomy:

13          1.          Its increased biomass demand would exacerbate competition for land and  
14          environmental impacts of crop production, and

15          2.          Farmers could not produce more with less and not overcome the ‘food vs fuel  
16          vs biomaterials’ conflict through improved cropping and integrated land use.

17          This work has evaluated the GWP impacts regarding improved N-use to reduce GHG  
18          emissions; future work needs to include possible C stock changes likely to arise from arable  
19          land converted to perennials. Secondly, this case study is speculative in the sense that the  
20          only empirical data available were for wheat and Miscanthus yields, as measurement for N  
21          fluxes were not available and solely based on models. Future work should also account for  
22          below- and above-ground C stock changes, both, in biomass and soil, which together with  
23          N-flux measurements would reduce the uncertainty of the models. Thirdly, this work is

1 limited to the case study area, so the methodology we proposed should also be tested with  
2 broader applications.

3

#### 4 6 ACKNOWLEDGEMENTS

5 We thank the European Commission's Climate-KIC programme for financial support  
6 provided in the context of the project Adaptation and Mitigation through Bio-Succinate  
7 Innovation (ADMIT Bio-SuccInnovate). Co-authors Qi and Richter acknowledge the  
8 support by the UK Engineering Physical Sciences Research Council (EPSRC), through grant  
9 EP/K036734/1 "Bioenergy value chains: Whole systems analysis and optimisation"  
10 (Supergen Bioenergy Challenge) and by Rothamsted Research's Institute Strategic  
11 Programmes "Soil to Nutrition" (BB/PO1268X/1) and "ASSIST" (BBS/E/C/000I0110)

1 **Table 4.** Life cycle inventory for wheat and Miscanthus cultivation used in this study.  
 2 Cultivation data for wheat is taken from the Biomass Environmental Assessment Tool (BEAT)  
 3 v2.1 database and from the Sustainable Liquid Biofuels from Biomass Biorefining (SUNLIBB)  
 4 project for Miscanthus.

	Unit	Wheat	Miscanthus
<b>Seeds</b>	kg /ha/year	175	0
<b>Rhizomes</b>	kg /ha/year	0	5921
<b>Ammonium nitrate<sup>a</sup></b>	kg N /ha/year	205	60
<b>Triple superphosphate</b>	kg P <sub>2</sub> O <sub>5</sub> /ha/year	39	7
<b>Potassium chloride</b>	kg K <sub>2</sub> O /ha/year	48	0
<b>Potassium sulphate</b>	kg K <sub>2</sub> O /ha/year	0	105
<b>Calcium oxide</b>	kg CaO /ha/year	0	175
<b>Manganese sulphate</b>	kg /ha/year	0	5.6
<b>Total pesticides (unspecified)</b>	kg /ha/year	1.03	1.15
<b>Total diesel consumption</b>	kg /ha/year	230	0.74
<b>Direct N<sub>2</sub>O emissions from soil<sup>b</sup></b>	kg N /ha/year	0.66	0.15
<b>NO<sub>3</sub><sup>-</sup> leaching<sup>b</sup></b>	kg N /ha/year	63.30	50.03
<b>Indirect N<sub>2</sub>O from NO<sub>3</sub><sup>-</sup> leaching</b>	kg N /ha/year	0.48	0.38
<b>Road transport (farm to storage)</b>	km	50	50
<b>Road transport (storage to plant)</b>	km	50	50
<b>Diesel (Loading &amp; Offloading)</b>	kg / kg feedstock	7.68E-04	7.68E-04

5 a. Ammonium nitrate input levels for winter wheat range from 160 to 220 kgN/ha/year, the weighted average value was  
 6 applied in this LCA work

7 b. DNDC simulated results, the weighted average value was applied in this LCA work (0.768 kg diesel per ton feedstock)

8

1 **Table 5.** Weighted average (and standard deviation) grain yield outputs and total annual  
 2 collectable straw in catchment area based on STAMINA-winter wheat

	<b>Baseline Climate</b>	<b>Medium Emission scenario</b>	<b>High Emission scenario</b>
<b>Wheat grain yield (t/ha 14.5% moisture)</b>	7.94 (0.39)	8.54 (0.12)	8.76 (0.11)
<b>Total collectable straw (kt/year 14.5% moisture)</b>	623.37	670.48	687.80
