ABSTRACT

'Bare' active galactic nuclei (AGN) are a subclass of Type 1 AGN that show little or no intrinsic absorption. They offer an unobscured view of the central regions of the AGN and therefore serve as ideal targets to study the relativistic reflection features originating from the innermost regions of the accretion disc. We present a detailed broad-band spectral analysis (0.3–70 keV) of one of the most luminous bare AGN in the local Universe, RBS 1124 $(z = 0.208)$ using a new, co-ordinated high signal-to-noise observation obtained by *XMM–Newton* and *NuSTAR*. The source exhibits a power-law continuum with $\Gamma \sim 1.8$ along with a soft excess below 2 keV, a weak neutral iron line and curvature at high energies (∼30 keV). The broad-band spectrum, including the soft excess and the high-energy continuum, is well fit by the relativistic reflection model when the accretion disc is allowed to have densities of log(*n_e/cm^{−3})* \gtrsim 19.2. Our analysis therefore suggests that when high-density effects are considered, relativistic reflection remains a viable explanation for the soft excess.

Key words: black hole physics – galaxies: active – X-rays: individual: RBS 1124.

1 INTRODUCTION

The X-ray spectra of Type 1 AGN are known to exhibit a *soft excess* below 2 keV, a feature characterized by a smooth excess flux over the primary continuum when extrapolated down to lower energies (Arnaud et al. [1985;](#page-9-0) Pounds, Done & Osborne [1995;](#page-10-0) Leighly [1999\)](#page-10-0). The origin of soft excess is still not clear and has been one of the longstanding mysteries in X-ray studies of AGN. It was initially believed to be the high-energy tail of blackblody emission from the inner disc (Arnaud et al. [1985;](#page-9-0) Magdziarz et al. [1998\)](#page-10-0). However, the disc temperatures derived from the models (0.1–0.3 keV) were deemed too hot to be considered as thermal emission from the accretion disc of an AGN (Porquet et al. [2004;](#page-10-0) Miniutti et al. [2009\)](#page-10-0). In addition, the

soft excess 'temperature' remains constant across several orders of magnitude of black hole mass and accretion rate (Crummy et al. [2006;](#page-9-0) Ponti et al. [2006;](#page-10-0) Done et al. [2012\)](#page-10-0). These findings essentially rule out thermal emission from the disc as the primary origin. Alternatively, it was later proposed that the soft excess could be produced by a smeared ionized relativistic absorption model, where the absorption features (oxygen edges) due to ionized relativistic winds originating in the inner parts of the accretion disc are broadened due to the relativistic motions of the wind (Gierlinski & Done [2004;](#page-10-0) Middleton, Done & Gierliński [2007\)](#page-10-0). This generates a deficit at ∼1 keV, creating the appearance of an excess at soft energies and spectral hardening at higher energies. However, simulations of such a wind model in Schurch & Done [\(2007\)](#page-10-0) show sharp features in the spectra and their calculations reveal that the winds do not achieve high enough relativistic speeds to produce absorption that is sufficiently smeared to explain the soft excess.

Currently there are two prevailing theories that are commonly used to describe the soft excess: the warm corona model (Magdziarz et al. [1998;](#page-10-0) Done et al. [2012;](#page-10-0) Petrucci et al. [2013\)](#page-10-0) and the blurred relativistic reflection model (Crummy et al. [2006;](#page-9-0) Zoghbi, Fabian & Gallo [2008;](#page-10-0) Walton et al. [2013\)](#page-10-0). Each of these models adopt different physical mechanisms to explain the soft excess. The warm corona model postulates the soft excess to be the result of Compton upscattering of disc photons from an additional corona, which is much cooler ($kT_e \sim 0.1 \,\text{keV}$) and has a much higher optical depth $(\tau = 20-40)$ compared to the 'hot' corona $(kT_e > 50 \text{ keV}, \tau \le 1)$ that generates the primary continuum. The blurred reflection model, on the other hand, implements the effects of special and general relativity (Fabian et al. [2000\)](#page-10-0) on the forest of emission lines within the reflection spectrum from an ionized disc at energies *<* 2 keV (Ross & Fabian [2005;](#page-10-0) García et al. [2013\)](#page-10-0), originating close to the innermost stable circular orbit of the supermassive black hole (SMBH). The blurred emission lines blend together, thereby reproducing the soft excess. The reflection origin scenario for the soft excess is further supported by the detection of soft lags, where the soft photons lag behind the hard X-ray continuum, as a result of the delay due to reverberation from the accretion disc (Fabian et al. [2009;](#page-10-0) Zoghbi et al. [2012;](#page-10-0) Kara et al. [2016\)](#page-10-0).

At present, it remains unclear which model is the primary origin of the soft excess. García et al. (2019) argued that the relatively cool temperature of the warm corona should result in numerous absorption features in the soft X-ray band, which do not seem to be observed. However, Petrucci et al. [\(2020\)](#page-10-0) later argued that the warm corona could remain completely ionized, thereby exhibiting no absorption/emission features in the soft energy band, if heating from the hot corona, the disc below, and internal heating processes are considered in their radiative transfer code, TITAN. While the debate between the warm corona and relativistic reflection models persists, some studies suggest that a combination of both models provides a more accurate explanation of the soft excess feature (Porquet et al. [2018,](#page-10-0) [2021;](#page-10-0) Xu et al. [2021;](#page-10-0) Xiang et al. [2022\)](#page-10-0).

In the context of a reflection scenario for the soft excess, it was recently shown that reflection from discs with densities higher than 10¹⁵ cm−³ can contribute towards the soft excess in a second manner as well. Reflection models by García et al. (2016) demonstrated that in a disc with higher density ($n_e > 10^{15}$ cm⁻³) there is a higher probability for free–free absorption, resulting in a rise in the disc temperature. Moreover, due to the quadratic dependence of free–free heating on density, the free–free continuum emissivity is enhanced, leading to a consequent increase in the reflection continuum. With this increase in the reflection continuum, along with the temperature rise in the disc, gas on the surface of the disc radiates like a blackbody, which can make a further contribution to the soft excess in the reflection interpretation (in addition to the blurred emission lines). Integrating variable disc densities with blurred relativistic reflection creates the high disc density relativistic reflection model, a promising tool for observing and understanding disc density. This high-density reflection model has successfully explained the soft excess component in several AGN without the requirement of any additional Comptonizing component (Jiang et al. [2019,](#page-10-0) [2022;](#page-10-0) Xu et al. [2021;](#page-10-0) Mallick et al. [2022;](#page-10-0) Yu et al. [2023\)](#page-10-0).

However, most of these high-density reflection studies have focused on the soft X-ray band (0*.*3–10 keV). There have been only a few instances where the model was tested with broad-band data sets of 'bare' AGN (which have little-to-no excess absorption above the Galactic column, and thus provide the best view of the soft excess; Matzeu et al. [2020;](#page-10-0) Porquet et al. [2021;](#page-10-0) Xu et al. [2021;](#page-10-0) Chalise et al. [2022\)](#page-9-0). This limited testing has resulted in a significant ongoing debate asto whether the high-density relativistic reflection model can adequately fit the broad-band data for these sources. Some analyses have suggested that, while the model can successfully fit data in the soft band, in some cases it appears to struggle to fit the full broad-band spectrum. For example, Matzeu et al. [\(2020\)](#page-10-0) reported that the high-density reflection model, though able to fit the soft Xray spectrum of Ton S180 with moderate density values (Jiang et al. [2019\)](#page-10-0), struggled to simultaneously explain both the soft excess and features beyond 10 keV when *NuSTAR* data was included. Porquet et al. [\(2021\)](#page-10-0) also report similar results when applying the model to Mrk 110. In contrast, for some bare AGN the relativistic reflection model can successfully model the available broad-band data (e.g. García et al. [2019;](#page-10-0) Xu et al. [2021\)](#page-10-0). Given these circumstances, it is crucial to continue testing the high-density reflection model on broadband observations to fully understand its potential. In this context, we decided to assess the high disc density relativistic reflection model using the bare AGN RBS 1124.

RBS 1124 (*z* = 0*.*208), also known as RX J1231.6+7044, was originally detected as an X-ray source during the *ROSAT All Sky Survey (RASS)*, and is one of the most luminous radio-quiet quasars in the local Universe ($L_{2-10 \text{ keV}} = 6 \times 10^{44} \text{ ergs s}^{-1}$; Miniutti et al. [2010\)](#page-10-0). It is categorized as a bare AGN with no/minimal intrinsic obscuration (Walton et al. [2013\)](#page-10-0), thereby offering an unobscured view of the central regions of the AGN and an ideal opportunity to study relativistic reflection features originating from the innermost regions of the accretion disc. RBS 1124 is spectroscopically classified as a broad line quasi-stellar object (QSO) with an H *β* line width of $(4.26 \pm 1.25) \times 10^3$ km s⁻¹ (full width at half maximum; Thomas et al. [1998\)](#page-10-0) and an optical luminosity at 5100 Å of $L_{5100} = 1.2 \times 10^{44}$ erg s⁻¹. Miniutti et al. [\(2010\)](#page-10-0) estimate the mass of the black hole to be around 1.8×10^8 M_o using the mass scaling relationship between H β line width and L_{5100} continuum luminosity (Vestergaard & Peterson [2006\)](#page-10-0).

Previous analysis of the *Suzaku* observation of RBS 1124 showed that the source had a moderately hard power-law continuum with photon index (Γ) of 1.94 \pm 0.02, a soft excess, a broad Fe-K α fluorescence line in the 0*.*5–10 keV band (Krumpe et al. [2010;](#page-10-0) Miniutti et al. [2010\)](#page-10-0), a Compton hump peaking between 15–25 keV in the hard Xray band (Walton et al. [2013;](#page-10-0) Waddell & Gallo [2020\)](#page-10-0), and radiatively efficient accretion with $L_{Bol}/L_{Edd} \simeq 0.15$. Although *Suzaku* offered a broad-band view of the source, *Suzaku*/PIN is a non-imaging highenergy detector (10–70 keV) which is dominated by background, hence providing a low signal-to-noise (S/N) ratio. Observations with high S/N broad-band coverage, combining *NuSTAR* and *XMM*– *Newton* for example, are vital for determining the presence of relativistic reflection from the disc, and for placing the most robust constraints on its properties (Risaliti et al. [2013;](#page-10-0) Brenneman et al. [2014;](#page-9-0) Walton et al. [2014;](#page-10-0) Kara et al. [2015;](#page-10-0) Marinucci et al. [2016;](#page-10-0) Buisson et al. [2018\)](#page-9-0). In this paper, we present a detailed broadband spectral analysis (0.3–70 keV) of RBS 1124 using a new, coordinated high S/N observation obtained with *XMM*–*Newton* and *NuSTAR*.

In the following sections, we introduce the observations used for our analysis (Section 2). The data analysis procedures and the modelling techniques are described in Section [3.](#page-3-0) In Section [4](#page-6-0) and [5,](#page-6-0) we present the results from our analysis and discuss their implications, respectively.

2 OB SE RVAT IO N S AND DATA REDUCTION

We use three new, co-ordinated high S/N observations obtained from *XMM*–*Newton* and *NuSTAR* taken during 2021. The log of

Obs.	Mission	Instrument	Observation	Start Date	Exposure time (s)
	<i>NuSTAR</i>	FPMA & FPMB	60 701 055 002	14/12/2021	135952
	XMM-Newton	PN. MOS & RGS	0.891.804.001	14/12/2021	30312
	XMM-Newton	PN. MOS & RGS	0.891.804.201	20/12/2021	32117

Table 1. Summary of the observations of RBS 1124.

Figure 1. *NuSTAR* (FPMA + FPMB) full band light curve for Obs. 1 with an exposure of 135 ks is plotted in blue. *XMM*–*Newton* (EPIC-PN) light curves for Obs. 2 and 3, in the full energy band, each having an exposure of ∼30 ks, are plotted in black and orange colours, respectively. All the light curves are binned to 1000 s.

the observations are given in Table 1. During this period the source did not show any specific variability (see Fig. 1) and so we focus our analysis on modelling the time-averaged spectrum obtained from these observations. We carried out a standard data reduction of the three observations and we analyse the data using two of the leading relativistic reflection models, which will be described in Sections [3.2](#page-4-0) and [3.3.](#page-4-0)

2.1 *XMM***–***Newton*

We used observations from the European Photon Imaging Camera (EPIC) and the Reflection Grating Spectrometer (RGS) instruments onboard *XMM*–*Newton*. EPIC includes three X-ray CCD cameras covering the 0.3–10 keV bandpass: two Metal Oxide Semiconductors (MOS1 and MOS2; Turner et al. [2001\)](#page-10-0) and a p-n CCD (PN; Strüder et al. [2001\)](#page-10-0). The two RGS detectors (RGS 1 $&$ 2) provide dispersive high-resolution spectroscopy over the 0.35–2 keV energy range (den Herder et al. [2001\)](#page-10-0).

The Observation Data Format files for both the *XMM*–*Newton* observations were retrieved from the *XMM*–*Newton* Science Archive (XSA) and reduced using the standard software package, the Science Analysis System (SAS), SASVERSION 20.0.0, maintained by the Science Operations Centre. All EPIC detectors were operated in Small Window mode for both observations. We then ran the reduction meta-tasks EMPROC and EPPROC to obtain the calibrated and integrated event lists for the MOS and PN detectors, respectively. The XMMSELECT task was invoked to generate the science products from these cleaned event lists. For the PN observations, a source region of 30" and a background region of 60" were chosen. For MOS observations, a source region of $40''$ and a background region of $160''$ were chosen. The standard additional filters were used during event selection: we only select events with PATTERN \leq 4 (single-double events) and PATTERN <12 (single-quadruple events) for the PN and MOS detectors, respectively, and ran our extraction with FLAG $== 0$ to exclude events close to CCD gaps and/or bad pixels. We used the EPATPLOT task to check whether there is any pile-up in the data, and this was found to be negligible. The response files for both PN and MOS detectors were generated using the RMFGEN and ARFGEN tasks. We thus obtained three sets of spectral files (from the PN, MOS1, and MOS2 detectors) for each observation. We also checked the spectra to see if the source exhibited any significant variability between the two observations. The overall shape of the spectra were similar without any significant variability. We therefore combined the PN spectra and the spectra from the MOS detectors (MOS1 and 2) for both epochs using the ADDASCASPEC task, resulting in a single set of spectral files for the PN detector, and a single set of spectral files for the combined MOS detectors. The final PN and MOS spectra were rebinned to have a minimum S/N of 10 per energy bin.

The RGS data were reduced using standard procedures, with both spectrometers operating in the 'Spectroscopy' mode for both observations. Clean event lists, light curves, spectra, and response files were generated using the RGSPROC task. Standard source and background extraction regions were used. The spectra from RGS 1 and 2 of both Obs 2 and 3 were merged into a single spectrum using the RGSCOMBINE task, after ensuring consistency in overall spectral shape across all four RGS data sets. To maintain maximum spectral resolution, the RGS data was binned to a minimum of 1 count per bin.

2.2 NuSTAR

NuSTAR (Harrison et al. [2013\)](#page-10-0) carries two identical, co-aligned X-ray telescopes that are sensitive over the 3–78 keV band (focal plane modules A and B; FPMA and FPMB). The data for both FPMA and FPMB were reduced with the *NuSTAR* Data Analysis Software (NUSTARDAS) V2.0.0, and *NuSTAR* calibration data base v20221115. The unfiltered event files were initially cleaned with NUPIPELINE. We used the standard depth correction to reduce the internal high-energy background, and passages through the South Atlantic Anomaly were removed using the following settings: SAA- $CALC = 3$, $SAA = OPTIMIZED$, and $TENTACLE = Yes$. Source light curves, spectra and their associated instrumental responses were then extracted from these cleaned event lists using NUPRODUCTS and a circular aperture of radius 70". The background contribution was estimated from a larger region of blank sky on the same chip as RBS 1124. In order to maximize the S/N, we extracted both the standard 'science' data (mode 1) and the 'spacecraft science' data (mode 6), following the procedure outlined by Walton et al. [\(2016\)](#page-10-0) in the latter case; the mode 6 data provide 19 per cent of the total good exposure for this observation. After performing the spectral extraction for FPMA and FPMB separately, these data were combined into a single *NuSTAR* spectrum using ADDASCASPEC, and the data were rebinned to have a minimum S/N of 5 per energy bin. The source is detected over the 3–70 keV energy range. Considering its redshift, it is worth noting that this *NuSTAR* detection extends to an intrinsic spectral energy of up to 85 keV, indicating a significant detection.

Figure 2. *Left*: the broad-band spectrum of RBS 1124 unfolded through a simple power law model. The data plotted in black, orange, and blue shows the PN, MOS, and *NuSTAR* data, respectively. *Right:* residuals obtained when plotting the data with respect to an absorbed power law. The data is fitted over the energy ranges 2–4, 7–10, and 30–70 keV and then extrapolated for the broad-band energies. The key signatures include the weak neutral iron line, soft excess and curvature at higher energies associated with a high energy cutoff.

3 SPECTRAL ANALYSIS

In this section, we analyse the time-averaged spectrum in the broad-band energy range (0.3–70 keV) and describe the model-setup procedure for fitting the spectrum. XSPEC V12.12.1 (Arnaud [1996\)](#page-9-0) is used to analyse our data and the errors we quote are the 90 per cent confidence interval for a single parameter of interest. Throughout this work, we use the *tbabs* neutral absorption code (Wilms, Allen & McCray [2000\)](#page-10-0) to model neutral hydrogen absorption within our Galaxy along the line of sight. The equivalent neutral hydrogen column density value (N_H) is fixed to 1.5 × 10²⁰ cm⁻² based on Winkel et al. [\(2016\)](#page-10-0). We also include a *constant* component to account for the cross-normalization factors between the three detectors (PN, MOS, and *NuSTAR*) for the joint fit.

The unfolded *XMM*–*Newton*+*NuSTAR* spectrum of RBS 1124, observed during December 2021, is shown in the left panel of Fig. 2. To start, we employed a simple *power law* model modified by Galactic absorption which we fit to the energy ranges of 2–4, 7–10, and 30–70 keV to emphasize the spectral features above the powerlaw continuuum; these are the energy ranges in which the primary AGN continuum is expected to be the dominant emission component. We then extrapolate this fit to the full bandpass considered here (0.3– 70 keV). The resulting data/model ratio is shown in the right panel of Fig. 2. The source spectrum is characterized by a primary continuum of $\Gamma = 1.72$. The source shows a soft excess below 1.5 keV with reference to the *power law*. We also detect a faint excess emission at ∼5*.*4 keV (observed frame), which is associated with the neutral iron line after accounting for the cosmological redshift of RBS 1124. Along with these features, we also observe curvature at high energies, which may indicate that we see the high-energy cutoff related to the electron temperature of the corona. Based on the residuals, we next investigate the presence of iron emission and update the broad-band X-ray spectral model.

3.1 RGS spectral analysis

Before proceeding with the broad-band analysis of the source, we first present a brief analysis of the RGS data to confirm the 'bare' nature of RBS 1124. The soft excess component is dominant across the energy range covered by RGS (0*.*35–2 keV), as seen in the right panel of Fig. 2. The merged RGS spectrum was initially modelled using the phenomenological baseline model, combining *power law*

and *blackbody* components to address the primary continuum and the soft excess, respectively. However, the *blackbody* contribution was unconstrained, and the continuum was well described by the *power law* alone, with no improvement from the *blackbody* inclusion. We therefore use the simpler *power law* continuum modified by Galactic absorption.

Due to the low count rates per channel in the RGS data, we use the Cash statistic (Cash [1979\)](#page-9-0) for spectral fitting. This model produced a good fit, with a C-statistic of 2834.5 for 2813 degrees of freedom (d.o.f) and a Γ of 2.00 \pm 0.05.¹ There were no obvious wind signatures in the RGS spectrum. However, slight residuals at ∼0*.*6 keV were observed (as shown in Fig. [3\)](#page-4-0). To investiagte these residuals, we added the multiplicative *XSTAR* table model to the *power law* model. This addition resulted in a marginal improvement with a ΔC -statistic of -12 for 3 d.o.f.

The best-fitting model parameters correspond to a moderatelyionized, low column density, ultrafast outflowing wind, with log $(\xi \text{ erg cm s}^{-1})$ = 1.6 ± 0.2, $N_H = 3.7^{+3.0}_{-2.4} \times 10^{20} \text{ cm}^{-2}$, and $v =$ $0.09 \pm 0.01c$, respectively. However, this marginal improvement in the fit statistics is not significant. Moreover, the combination of such a fast outflow velocity with a low-ionization parameter is unusual, and not typical of most of the 'ultrafast' outflows claimed in literature (Tombesi et al. [2010;](#page-10-0) Gofford et al. [2013;](#page-10-0) Reeves et al. [2018\)](#page-10-0). Therefore, we also performed fits with the outflow velocity set to zero and the ionization parameter capped at an upper limit of 3 to closely mimic a typical warm absorber (McKernan, Yaqoob & Reynolds [2007;](#page-10-0) Laha et al. [2014;](#page-10-0) Gallo, Miller & Costantini [2023\)](#page-10-0). We found that including an ionized absorber with low outflow velocity did not improve the fit at all. The upper limit on the column density was constrained to $N_{\text{H}} < 6 \times 10^{21} \text{ cm}^{-2}$, placing RBS 1124 at the lower end of the N_H distribution seen in warm absorbers from other systems (Laha et al. [2014;](#page-10-0) Yamada et al. [2024\)](#page-10-0), thereby affirming the 'bare' nature of RBS 1124.

¹The *power law* now accounts for the soft excess over the RGS bandpass, resulting in a steeper Γ value than the one obtained in the broad-band analysis later on (see Section [4\)](#page-6-0). For completeness, we also tried fixing Γ to the value implied by the broad-band analysis $(\Gamma = 1.8)$ and reintroducing the *blackbody* component for the soft excess. This did not change any of the conclusions regarding the presence of the absorption obtained with the simpler *power law* continuum.

Figure 3. The spectral fit of RGS data using a simple *power law* modified by Galactic absorption is shown in the upper panel. The black points represent the data, and the red solid line represents the model. The bottom panel illustrates the residuals against the absorbed *power law* model. The RGS spectrum has been rebinned for plotting purposes.

No significant emission lines were detected in the RGS spectrum, including the O VII triplet recently reported in similar bare AGN (Reeves et al. 2016 ; Porquet et al. [2024\)](#page-10-0). Assuming a line width (σ) of 3.5 eV^2 , the most conservative upper limit on the equivalent width (EW) of the O VII triplet emission was constrained to EW *<* 3*.*8 eV for a forbidden transition at a rest-frame energy of 561 eV. This limit is comparable to the constraints reported by Reeves et al. [\(2016\)](#page-10-0) and Porquet et al. [\(2024\)](#page-10-0) for the O VII intercombination and resonant lines, respectively, with EWs *<* 3*.*3 eV and *<* 3*.*1 eV. This suggests that while features of similar strength could be consistent with our data, we do not detect them in RBS 1124.

3.2 Iron emission

The data show an emission line at ∼6*.*4 keV in the rest frame of RBS 1124 (see Fig. [2\)](#page-3-0). This feature is naturally interpreted as fluorescent emission from iron (George & Fabian [1991;](#page-10-0) Nandra et al. [2007\)](#page-10-0). Since the line is weak, we initially model it using a basic redshifted Gaussian model, *zgauss*. We tried fitting the data in the 2–10 keV energy band using the model *tbabs*×*(zgauss* + *power law)*, leaving the width of the emission line free to vary. We could only find an upper limit for the line width, σ < 0.3 keV. We therefore fixed the line width to $\sigma = 1$ eV, i.e. below our spectral resolution, assuming a narrow core iron line. This model combination gave a good fit with a χ^2 of 981 for 996 d.o.f. and a line EW of 42 ± 17 eV. This EW and $L_{2-10 \text{ keV}} = 6 \times 10^{44} \text{ erg s}^{-1}$ (Miniutti et al. [2010\)](#page-10-0) agree with the EW-luminosity trend seen for AGN narrow iron emission lines due to the X-ray Baldwin effect (a known anticorrelation between the EW of the narrow emission line from neutral iron and 2–10 keV X-ray luminosity of AGN, also known as the Iwasawa–Taniguchi effect; Iwasawa & Taniguchi [1993;](#page-10-0) Bianchi et al. [2007\)](#page-9-0). We also

3.3 Broad-band analysis

After focusing on the iron band specifically, we now explore whether the high-density relativistic reflection model offers a viable interpretation of the soft excess in RBS 1124. We use the Comptonization model *nthcomp* (Zdziarski, Johnson & Magdziarz [1996;](#page-10-0) Życki, Done & Smith [1999\)](#page-10-0) for the primary continuum of the source. The effects of cosmological redshift are convolved with the primary continuum using the *zashift* model. The weak neutral iron line, which is likely a result of distant reflection from the torus, is fitted using the table model *borus*³ (Baloković, García & Cabral [2019\)](#page-9-0). The *borus* model assumes the reprocessing medium to have a spherical geometry with conical cutouts at the poles. Considering the bare nature of RBS 1124, we set up the *borus* component in a way that its covering factor, $cos(\theta_{tor})$ is always less than the inclination angle, $cos(\theta_{inc})$. This ensures that the distant reflection is computed assuming that we do not look through the torus itself, but rather it is out of our line of sight. The photon index (Γ) and the electron temperature (kT_e) values are linked between the *nthcomp* and the *borus* model components.

We try to model the disc reflection using two currently prominent reflection models: *xillverCp* (García & Kallman [2010;](#page-10-0) García et al. [2013\)](#page-10-0) and *reflionx*⁴ (Ross & Fabian [2005\)](#page-10-0). *xillverCp* is an extension of *xillver* – an ionized reflection table model (García & Kallman 2010) and is included in the RELXILL family of models (García et al. [2014\)](#page-10-0). *reflionx* is an ionized reflection table model developed by Ross & Fabian [\(2005\)](#page-10-0). The latest versions of both models use *nthcomp* asthe incident primary continuum and allow the disc density to vary within the range 10^{15} – 10^{20} cm⁻³. While using either model, the key parameters describing the ionizing continuum, i.e. Γ and *kT*e, are tied to the relevant parameters in the *nthcomp* component. The other key reflection parameters, such as the iron abundance $(A_{\text{Fe}})^5$, ionization parameter (*ξ*) and density (*n*_e) of the disc are left free to vary. In order to apply the relativistic effects to the non-relativistic reflection spectrum, we use the convolution model *relconv* (Dauser et al. [2010,](#page-9-0) [2013\)](#page-9-0). The *relconv* model assumes the emissivity profile of the accretion disc to have a broken power law in the form: $\epsilon(r) \propto r^{-q_{\text{in}}}$ for $r_{\text{in}} \leq r \leq r_{\text{br}}$ and $\epsilon(r) \propto r^{-q_{\text{out}}}$ for $r_{\text{br}} \le r \le r_{\text{out}}$, where q_{in} and q_{out} denote the inner emissivity index and outer emissivity index, respectively. r_{in} , r_{out} , and r_{br} are the inner radius, outer radius and the break radius of the accretion disc. We allow r_{br} , q_{in} , the spin parameter (a^*) and the inclination angle *(i)* to vary, while we assume that for $r > r_{br}$ the emissivity can be well approximated by the Newtonian limit, and thus adopt a fixed value of $q_{\text{out}} = 3$ for the outer emissivity index (Reynolds & Begelman

²The line width is fixed at $\sigma = 3.5$ eV based on the broad lines observed in this source (FWHM (H β) ~ 4250 km s⁻¹; Grupe et al. [2004\)](#page-10-0), which is also consistent with the widths of the lines from the O VII triplet in Reeves et al. [\(2016\)](#page-10-0) and Porquet et al. [\(2024\)](#page-10-0).

³We use the borus12_v190815a.fits file available at [https://sites.astro.caltech.](https://sites.astro.caltech.edu/~mislavb/download/) edu/∼mislavb/download/

⁴We use the reflionx_HD_nthcomp_v2.fits file available at https://www. [michaelparker.space/reflionx-models.](https://www.michaelparker.space/reflionx-models)

⁵We assume (A_{Fe})_{borus} = 0.7 \times (A_{Fe})_{xillver/reflionx}, to account for the varying values assumed for the solar abundance of iron in *borus* and *xillver/reflionx* model components.

[1997;](#page-10-0) Fabian et al. [2012b\)](#page-10-0). We therefore have two resultant models to describe the relativistic reflection component within the broadband spectrum: *relconv*⊗*xillverCp* (hereafter referred to as Model 1) and *relconv*⊗*reflionx* (Model 2). It is worth noting that Model 1 can essentially be replaced by *relxillCp*, which is also a part of the broad RELXILL model ensemble (García et al. [2013\)](#page-10-0). However, such a substitution cannot be extended to *reflionx*. To maintain consistency between the two models considered here, we opt to use *relconv*⊗*xillverCp/reflionx*.

Model 1, along with the *tbabs*, *nthcomp*, and *borus* components discussed above, gives an excellent fit with χ^2 /d.o.f. of 1913.9/1894. The relative contributions from the different model components for the best-fitting parameter combination in Model 1 are shown in the left panel of Fig. 4 and the best-fitting parameter constraints are given in Table 2. The model fits all the features in the broad-band energy range relatively well. However the data at higher energies

Figure 5. Data-to-model ratio for the best fit obtained from Model 1 (top) and Model 2 (bottom). Note that the colours have the same meanings as in Fig. [2.](#page-3-0)

slightly deviate from the fit. The data-to-model ratio plot for Model 1 is shown in panel M1 of Fig. 5. Model 2 gives a slightly improved fit with a $\Delta \chi^2$ of −3 and also fits the data at higher energies (see panel M2 in Fig. 5). The relative contributions for the best-fitting parameters in Model 2 and these parameter constraints are again presented in Fig. 4 and Table 2, respectively. The results obtained from each fit are discussed in Section [4.](#page-6-0)

Along with parameters directly included in the models used here, we also compute the reflection fraction ($R = \Omega/2\pi$) for both our model fits following the methodology described in Walton et al. [\(2013\)](#page-10-0). The reflection fraction provides insights into the geometry of the disc–corona system. Reflection fraction (R) conventionally refers to the ratio of the reflected flux (F_{Ref}) to the Comptonized flux (F_{Com}). For a semi-infinite slab in an ideal non-relativistic scenario, the accretion disc covers a solid angle (Ω) of 2π steradians as seen from the corona, which is traditionally defined as a reflection fraction of 1. To estimate the reflection fractions implied by our fits, we calculate the flux ratios between the reflection and the primary continuumin the

15–50 keV band (as this energy band is dominated by the Compton scattering processes and is not strongly influenced by the ionization state of the disc) prior to the application of any relativistic blurring, and then compare this to the equivalent flux ratio predicted by the *xillverCp* model for $R = 1$ for the same set of key spectral parameters (Γ, i, ξ) and A_{Fe}). These values are also reported in Table [2.](#page-5-0) Note that even though they are based on a flux ratio, since they are scaled to the $R = 1$ case from *xillverCp* they should be broadly analogous to the definition of the reflection fraction discussed in Dauser et al. [\(2016\)](#page-9-0), as opposed to the reflection 'strength' also discussed in that work (which is a flux ratio), even if our definitions are not exactly the same.

We also perform Markov chain Monte Carlo (MCMC) analysis to explore the parameter space to get robust constraints on parameters. The CHAIN command within XSPEC was invoked to do the MCMC analysis. We use the Goodman–Weare (GW) algorithm with 60 walkers and a chain length of 30 000 for each walker and a burn length of 5000, thus giving a total chain length of 1500 000. Errors for the parameters quoted in Table [2](#page-5-0) are estimated based on these chain values. The integrated posterior distribution for each parameter is as shown in Figs $A1$ and $A2$ (in Appendix A) for Models 1 and 2, respectively. Error estimates for several parameters are consistent across both the models.

4 RESULTS

Models ¹ and ² produce equally good fits with *^χ*2/d.o.f. [∼] ¹*.*⁰¹ and the parameters obtained from both the models are broadly consistent (see Table [2\)](#page-5-0). Γ values of 1.76^{+0.03} and 1.80^{+0.02}, obtained from Models 1 and 2 respectively, are in fair agreement with the Γ value obtained by previous works ($\Gamma \sim 1.85$; Miniutti et al. [2010;](#page-10-0) Walton et al. [2013\)](#page-10-0). Both models predict a high-density disc for RBS 1124 with $\log(n_e/cm^{-3})$ > 19.2. While Model 1 could only achieve a lower limit to the density value, Model 2 provides two-sided limits on the density with $\log(n_e/cm^{-3}) = 19.48^{+0.28}_{-0.31}$. We observe that, for a given density value, the *reflionx* model generates higher flux for the reflected continuum at energies below 1 keV compared to the *xillverCp* model, which allows it to effectively account for the soft excess at slightly lower densities within the range covered by these models. Consequently, its lower best-fitting density allows *reflionx* to provide two-sided constraints, while its higher best-fitting density means the *xillverCp* confidence limits run up against the current upper limit of the model.

Model 1 prefers a highly spinning black hole $(a^* > 0.865)$, whereas Model 2 presents notably weaker constraints on the spin $(a^* > 0.236)$. Variation in χ^2 as a function of a^* , obtained by stepping *a*[∗] using the STEPPAR command in XSPEC, for Models 1 and 2 are presented in the Fig. 6. This is related to the same issue as highlighted above; the stronger reflection continuum at low energies in *reflionx* means this model does not need to rely so heavily on the line emission to reproduce the overall soft X-ray flux. In contrast, *xillverCp* shows a stronger need for extreme line broadening in order to produce a smooth soft excess, as the lines make a larger relative contribution to the soft excess. The different relative levels of the reflection continuum at low energies in the two models relates to differences in the fine details of the calculations performed, e.g. the atomic physics included, the treatment of scattering, and the treatment of resonant emission lines. These factors dictate the level of photoionized absorption, the strength of key emission lines and the energy at which the low-energy continuum from free–free emission peaks, all of which can impact the flux of the reflection model at the lowest energies in the observed bandpass in particular.

Figure 6. Variation of fit-statistic by stepping the spin parameter a^* away from the best fit for both Model 1 (red) and Model 2 (black). The dotted lines signify the 90 per cent, 95 per cent, and 99 per cent confidence intervals, respectively.

Model 1 yields an iron abundance (A_{Fe}) in the range 0.7–1.2, consistent with the solar value, while Model 2 shows an abundance value *<* 0*.*7. Both are lower than the constraint obtained previously $(A_{\text{Fe}} = 2.7^{+1.8}_{-0.9}$; Walton et al. [2013\)](#page-10-0). This difference may be attributed to the implementation of a variable-disc density model in this work. According to discussions in Tomsick et al. [\(2018\)](#page-10-0) and Jiang et al. [\(2019\)](#page-10-0), the high-density disc model leads to an increase in the continuum within the reflection component around the iron line, thus giving lower iron abundances when compared to the results obtained fitting older models in which the density was fixed to 10^{15} cm⁻³. The emissivity index could not be well constrained in our analysis. A lower limit of 3.94 was obtained from Model 2. The break radius is also poorly constrained, with $R_{\text{br}} > 3.01 R_{\text{ISCO}}$. High ionization values were obtained from our fit, while the previous analyses of the source find lower values for ionization (*^ξ* [≤] ¹⁰⁰ erg cm ^s−1; Miniutti et al. [2010;](#page-10-0) Walton et al. [2013;](#page-10-0) Tripathi et al. [2019\)](#page-10-0). Our reflection modelling implies that the source is viewed at a low inclination $(i < 43°)$, which is in line with broad expectations for the unified model given the bare nature of RBS 1124.

5 DISCUSSION

We present a broad-band $(0.3-70 \,\text{keV})$ spectral analysis of the broad line Sy 1 AGN RBS 1124, using a new co-ordinated *XMM*–*Newton* and *NuSTAR* observation. The spectrum exhibits features typically observed in 'bare' AGN: a soft excess and weak distant reflection along with the primary X-ray continuum. Our work focuses on investigating the relativistic reflection model for the soft excess seen in this source, given the ongoing debate in the literature regarding its ability to explain the broad-band data sets available for bare AGN (García et al. [2019;](#page-10-0) Matzeu et al. [2020;](#page-10-0) Porquet et al. [2021;](#page-10-0) Xu et al. [2021\)](#page-10-0). We emphasize that the warm corona model remains a well-established alternative for the soft excess. However, there is not a corresponding debate, as this model is invariably capable of reproducing the broad-band spectrum for bare AGN, since the soft and hard X-ray components are essentially de-coupled from a fitting perspective. In this context, we concentrate on testing the compatibility of the high-density reflection model with the broad-band data for RBS 1124, focusing on whether this model can reproduce the full spectral range. This study marks the first application of variable-density relativistic reflection models to RBS 1124, and we test both of the reflection models commonly used in the recent literature (*xillver* and *reflionx*). As discussed in more detail below, we find that high-density relativistic reflection model

Downloaded from https://academic.oup.com/mnras/article/534/1/608/7754166 by guest on 18 October 2024 Downloaded from https://academic.oup.com/mnras/article/534/1/608/7754166 by guest on 18 October 2024

can indeed reproduce the broad-band spectrum seen from this bare AGN.

Previous studies of this source used fixed density relativistic reflection models ($n_e = 10^{15}$ cm⁻³) to describe the broad-band spectrum (Miniutti et al. [2009;](#page-10-0) Walton et al. [2013;](#page-10-0) Tripathi et al. [2019\)](#page-10-0). These models solely relied on the relativistic blurring of emission lines to explain the soft excess, resulting in tighter constraints on earlier spin measurements. Our analysis yields spin constraints that, while formally weaker than these previous relativistic blurring studies, are likely more realistic owing to the higher S/N data over a broader bandpass and the inclusion of disc density as a free parameter in our models. Similarly, prior studies inferred varying reflection fractions using low S/N *Suzaku* PIN data: Walton et al. [\(2013\)](#page-10-0) inferred a large reflection fraction for RBS 1124 ($R \sim 3$), while Miniutti et al. [\(2009\)](#page-10-0) found a much lower value ($R \simeq 0.4$) from the same data. Our results with the much better *NuSTAR* high-energy data suggest the latter interpretation is more reliable.

5.1 General properties of the primary continuum

The corona around an SMBH is characterized by two key parameters: photon index (Γ) and high-energy cut-off (E_{cut}) . E_{cut} is directly associated with the plasma temperature (kT_e) by the relation $E_{\text{cut}} = (2 - 3)kT_e$ (Petrucci et al. [2001\)](#page-10-0). The parameters Γ and kT_e are directly estimated from the spectral fitting through the Comptonizing model component. Our best-fitting model indicates $a \Gamma = 1.80 \pm 0.01$ for the primary continuum of RBS 1124, which agrees well with the typical value of 1.80 ± 0.02 seen in unobscured AGN (Ricci et al. [2017;](#page-10-0) see also Nandra & Pounds [1994\)](#page-10-0). We obtain a lower limit on kT_e ($> 34 \,\text{keV}$) from our best fit. Note that although Γ had been extensively monitored previously for this source (see Section [4\)](#page-6-0), kT_e could not be previously constrained due to limitations on coverage and data quality in the high-energy band-pass prior to *NuSTAR*. The relation between E_{cut} for the Comptonizing plasma and Eddington ratio (λ_{Edd}) was investigated by Ricci et al. [\(2018\)](#page-10-0) by studying a sample of 317 unobscured AGN. Their results show a median value of $E_{\text{cut}} = 160 \pm 41 \text{ keV}$ for the sample for sources with $\lambda_{\text{Edd}} > 0.1$. For a bolometric luminosity (L_{Bol}) of 3.4×10^{45} erg s⁻¹ (Grupe et al. [2004\)](#page-10-0) and an Eddington luminosity (L_{Edd}) of 2.3 × 10⁴⁶ erg s⁻¹ given the mass 1.8×10^8 M_o (Miniutti et al. 2010), RBS 1124 is inferred to be accreting with λ_{Edd} of 0.145. Our *E*cut and *λ*Edd values are consistent with Ricci et al. [\(2018\)](#page-10-0). These results indicate that RBS 1124 shows the typical plasma characteristics exhibited by unobscured AGN.

5.2 Soft excess and the high disc density of RBS 1124

The soft excess has consistently appeared as a prominent characteristic in the X-ray spectra of unobscured Sy1 AGN accreting with $\lambda_{\text{Edd}} \geq 0.01$, yet its true origin remains unclear. Currently, two leading models, namely the the warm corona model and the relativistic reflection model, try to explain the origin of the soft excess. Both models adopt distinct physical assumptions about the origin of this emission, with diverse insights into the properties of the inner accretion flow. The warm corona model invokes a radially stratified accretion flow, and thus potentially provides insight into how this stratification occurs (Petrucci et al. [2013;](#page-10-0) Kubota & Done [2018\)](#page-10-0). In contrast, the relativistic reflection interpretation invokes reprocessing of the hard X-ray radiation by the innermost accretion flow, and potentially provides insight into the ionization state and composition of the accretion flow as well as the geometry of the illuminating X-ray source. The high-density models are a recent evolution of this latter interpretation (García et al. [2013;](#page-10-0) Walton et al. [2013;](#page-10-0) Mallick et al. [2022\)](#page-10-0).

Reflection from the inner disc also gives information about the spin of the black hole, by assessing the extent of the relativistic effects that broaden the observed reflection spectrum (Iwasawa et al. [1996;](#page-10-0) Crummy et al. [2006;](#page-9-0) Walton et al. [2013;](#page-10-0) Reynolds [2021\)](#page-10-0). The spin measurements of SMBHs serve as important tracers of their growth history, as their formation and evolutionary trajectories are reflected on the mass and spin of the SMBHs (Piotrowska et al. [2024\)](#page-10-0). For instance, SMBHs formed via steady radiatively-efficient accretion are expected to exhibit rapid rotation. On the other hand, SMBHs formed via mergers are expected to exhibit moderate spin values, as the merger events typically reduce spin of the black hole (Hughes & Blandford [2003;](#page-10-0) Volonteri et al. [2005;](#page-10-0) Pacucci & Loeb [2020\)](#page-10-0). Therefore, a comprehensive mass-spin distribution of SMBHs would help distinguish the different evolutionary paths they have followed. Moreover, spin of the black hole may influence its efficiency in generating powerful relativistic jets (Blandford & Znajek [1977\)](#page-9-0) making robust spin measurements all the more crucial. Studying the relativistic reflection from the innermost accretion disc isthe leading method for measuring black hole spin in active galaxies, and so it is critical to assess the degree to which the soft excess is related to this emission.

A key part of determining the origin of the soft excess is testing these models against the best data available. For the reflection model, this requires broad-band spectroscopy as soft excess is assumed to be part of the broader reflection spectrum, which has key features in the iron band and in the hard X-ray band. We focus on testing this model using our new broad-band data set on the bare AGN RBS 1124 along with the very latest variable-density reflection models. It is worth noting again that there are still only limited instances where high S/N broad-band spectra are available for the bare AGN that are ideally suited to such observational tests, and that there are various conflicting claims in the literature about whether the reflection model provides acceptable fits to the data in these cases (Porquet et al. [2018;](#page-10-0) García et al. [2019\)](#page-10-0). We find that the reflection model does indeed fit the broad-band data well for RBS 1124, and seems to give broadly sensible results in terms of the primary continuum properties (see Section [3.3\)](#page-4-0) and the inferred inclination of $i < 43^\circ$ is as expected for a bare AGN based on the unified model (Antonucci [1993\)](#page-9-0), both of which are useful sanity checks.

Another key characteristic of the more recent evolution of the relativistic reflection model is that it offers a rare opportunity to place observational constraints on the density of the inner disc (Jiang et al. [2019;](#page-10-0) Mallick et al. [2022\)](#page-10-0). The density of a radiation pressure dominated accretion disc, as described by equation 8 in the disc– corona model of Svensson & Zdziarski [\(1994\)](#page-10-0), is given by

$$
n_{\rm e} = \frac{1}{\sigma_{\rm T}} \frac{256\sqrt{2}}{27} \alpha^{-1} R^{3/2} \dot{m}^{-2} [1 - (R_{\rm in}/R)^{1/2}]^{-2} \xi'(1 - f)^{-3},\tag{1}
$$

where $\sigma_T = 6.64 \times 10^{-25}$ cm² is the Thomson cross-section; *m* is the dimensionless accretion rate expressed in terms of the Eddington luminosity ($\dot{m} = \dot{M}c^2 L_{\text{Edd}}^{-1}$), R_{in} is the inner radius of the disc and is set to R_{ISCO} of a maximally spinning black hole; R_s is the Schwarzschild radius; *R* is the disc radius in units of R_s ; α is the viscosity parameter of the disc and is set to 0.1; ξ' is the conversion factor in the radiative diffusion equation and chosen to be 1 and *f* is the ratio of power dissipated to the corona from the disc varies between 0 and 1 (reducing to the standard thin disc solution of Shakura & Sunyaev [1973](#page-10-0) in the former limit). As a key parameter in this disc–corona model, accurate determinations of density play a key role in determining its viability. We cannot statistically distinguish

Figure 7. Variation of the disc density log(*n*e/cm−3) with respect to the product of mass of the black hole (m_{BH}) and \dot{m}^2 (where $\dot{m} = \dot{M}c^2L_{\text{Edd}}^{-1}$ is the dimensionless accretion rate expressed in terms of the Eddington luminosity). The points in the background correspond to a combined sample of 17 Sy 1 AGN (Jiang et al. [2019\)](#page-10-0) and 13 low mass AGN from (Mallick et al. [2022\)](#page-10-0), plotted in black and blue points, respectively. Sy 1 IRAS 13 224 (Jiang et al. [2022\)](#page-10-0), Sy 1 AGN Mrk 1044 (Mallick et al. [2018\)](#page-10-0), and ESO 362-G18 (Xu et al. [2021\)](#page-10-0) are additionally included in the background sample as triangle, diamond, and star shaped data points, respectively. Upward and downward arrowsindicate that only lower and upper density limits could be derived from the analysis. The upward arrow in red, highlighted in the foreground, shows the position of RBS 1124 in the diagram. The solid lines denote solutions of the density of the radiation pressure dominated accretion disc for *f* values of 0*,* 0*.*4*,* 0*.*7*,* 0*.*9, and 0.99. See text for details.

between the *reflionx* and *xillver* reflection models, but the combined implication of our analysis is that RBS 1124 has an inner disc density log (n_e /cm^{−3}) ≥ 19.2.

Among the relatively small sample of other AGN where variabledensity reflection models have been applied (Jiang et al. [2019;](#page-10-0) Mallick et al. [2022\)](#page-10-0), a broad anticorrelation has been observed between the density (n_e) and the mass of the SMBH (m_{BH}) . RBS 1124, hosting a SMBH with a mass of 1.8×10^8 M_o, initially seems to stand apart from other Sy 1 AGN as our results suggest it has a high density for the inner disc with $\log(n_e/cm^{-3}) > 19.2$. Nevertheless, for a radiation pressure dominated accretion disc, the density of the disc is expected to be anticorrelated to both m_{BH} and \dot{m}^2 , by the relation $log(n_e) \propto -log(m_{BH} \dot{m}^2)$, based on equation [\(1\)](#page-7-0).

In case of RBS 1124, for $\dot{m} = 0.145$, we estimate $\log(m_{\text{BH}}\dot{m}^2)$ = 6.57 ± 0.6 dex⁶ Fig. 7 shows log(n_e /cm^{−3}) versus log(m_{BH} *m*²) for a combined sample of Type 1 AGN from Mallick et al. [\(2018\)](#page-10-0), Jiang et al. [\(2019\)](#page-10-0), Xu et al. [\(2021\)](#page-10-0), Mallick et al. [\(2022\)](#page-10-0), and Jiang et al. [\(2022\)](#page-10-0). The red arrow in the figure represents the constraints we can place for RBS 1124, indicating its position relative to the rest of the Sy 1 AGN shown. Although the density of RBS 1124 obtained from our analysis is relatively high compared to other AGN, it still generally adheres to the anticorrelation proposed by Svensson & Zdziarski [\(1994\)](#page-10-0), considering the wide scatter observed in other AGN. The solid lines in the figure represent solutions for the density of a radiation pressure dominated disc (equation [1\)](#page-7-0) for different values of *f* . Given the position of RBS 1124 in the $log(n_e/cm^{-3})$ versus $log(m_{BH}m^2)$ plane, it can be inferred that more than 90 per cent of the power is dissipated to the corona from the disc. While the coronal dissipation fraction in RBS 1124 seems high compared to the Jiang et al. [\(2019\)](#page-10-0) sample, such high values have been seen previously. IRAS 13224–3809 (Jiang et al. [2022\)](#page-10-0) and Mrk 509 (García et al. [2019\)](#page-10-0) both exhibit dissipation fraction values exceeding 0.85. A similar study on a group of high-mass NLSy1s at high redshifts revealed that more than 95 per cent of the power seems to be dissipated in the corona in the case of E1346+266 (Yu et al. [2023\)](#page-10-0).

5.3 Reflection strength

The reflection strength gives information about the geometry of the corona and the proximity of the inner edge of the accretion disc to the central black hole. A compact corona located right above the event horizon of a rapidly spinning SMBH can exhibit high reflection strengths, due to the effects of light bending (Miniutti & Fabian [2004;](#page-10-0) Fabian et al. [2012a;](#page-10-0) Dauser et al. [2014,](#page-9-0) [2016;](#page-9-0) Parker et al. [2014;](#page-10-0) Walton et al. [2021\)](#page-10-0). The reflection strength however tends to converge to the standard non-relativistic case $(R = 1)$, for sources with low-spin or when the compact corona is located at a larger height (Dauser et al. [2016\)](#page-9-0). The impact of the black hole spin and height of the corona on the reflection strength has been extensively studied for a lamp-post model of the corona, which is likely a simplified representation of the real coronal geometry for many AGN. In our work, we do not prescribe any specific coronal geometry. Instead, we assume a broken power-law emissivity profile for the reflected spectrum, a profile that can be produced by a range of coronal geometries.

Although the spin and emissivity index values could not be tightly constrained, our fits did establish lower limits for both parameters. Our analysis suggests a moderately spinning black hole with $a^* > 0.236$ and an emissivity index $q_1 \gtrsim 3.94$. These values typically correspond to standard reflection strength ∼1 (Magdziarz & Zdziarski [1995\)](#page-10-0). However, our estimates show reflection strength values of 0.4 and 0.2 for Models 1 and 2, respectively, consistent with the findings of Miniutti et al. [\(2010\)](#page-10-0) who estimated an *R* value of 0.4. These values,significantly lessthan 1, could be indicative of an outflowing corona (Beloborodov [1999\)](#page-9-0), where corona is accelerated away from the disc at mildly relativistic velocities by radiation pressure (Gallo et al. [2007;](#page-10-0) Gonzalez et al. [2020;](#page-10-0) Wilkins et al. [2022\)](#page-10-0). Consequently, coronal X-rays are preferentially emitted upward, away from the disc, resulting in direct observation as continuum emission, leading to diminished illumination of the disc and a reduced reflection strength.

5.4 Absence of observable wind signatures

Ionized wide-angle outflows are ubiquitous features in accretionpowered sources (Blandford & Payne [1982;](#page-9-0) Proga, Stone & Kallman [2000;](#page-10-0) Proga & Kallman [2004;](#page-10-0) Giustini & Proga [2019\)](#page-10-0). AGN accreting at moderate – high accretion rates ($\dot{m} > 0.1$) are expected in particular to launch radiation-driven accretion disc winds (Proga & Kallman [2004;](#page-10-0) Risaliti & Elvis [2010\)](#page-10-0). These winds manifest as

⁶We assume that the uncertainty here is dominated by uncertainty in the black hole mass. The quoted uncertainty therefore combines in quadrature the 0.4 dex scatter on the scaling relation between m_{BH} , L_{5100} , and H β line width (Vestergaard & Peterson [2006\)](#page-10-0) used to estimate the mass of RBS 1124, and the 0.4 dex uncertainty on the reverberation mapping results used to calibrate this scaling relation (Peterson [2014\)](#page-10-0).

blueshifted absorption lines in the spectrum of X-ray sources (Ueda et al. [2004;](#page-10-0) Cappi 2006; Miller et al. [2006;](#page-10-0) Schurch, Done & Proga [2009\)](#page-10-0) and are commonly observed in AGN (Reynolds [1997;](#page-10-0) Crenshaw, Kraemer & George 2003; Tombesi et al. [2010;](#page-10-0) Laha et al. [2014\)](#page-10-0).

The absence of detectable wind signatures in RBS 1124, despite its moderately high mass accretion rate ($\dot{m} \sim 0.14$), is somewhat unexpected. While we cannot definitively conclude the absence of winds based solely on X-ray spectroscopy, we can propose plausible explanations for their absence in the X-ray spectrum. One plausible explanation is the viewing angle, which in the case of RBS 1124 is close to face-on, consistent with its Type 1 classification as per the unification theory. In Type 1 systems with equatorial winds, our line of sight may not directly intercept with the winds. However, there could be other sight lines where the winds are observable. Optical spectroscopic studies of the source could offer further insights into the nature of the outflows in the system. For instance, RBS 1055 is one of the brightest radio-quiet AGN detected in the ROSAT survey, with a luminosity of $\log(L_{(0.5-2 \text{ keV})}/[\text{erg s}^{-1}]) = 45.3$ and $\lambda_{\text{Edd}} = 0.13$, broadly similar to RBS 1124. It also exhibits comparable spectral characteristics to RBS 1124, including a soft excess and a narrow unresolved iron emission line, but no obvious detections of wind features in the X-ray spectrum (Krumpe et al. [2010\)](#page-10-0). Nevertheless, RBS 1055 showed blue-shifted O[III] lines in the optical spectrum, suggesting outflows in the Narrow Line Region, possibly driven by winds from the accretion disc (Marinucci et al. [2022\)](#page-10-0). Further analysis through optical spectroscopy can provide additional insights into the presence or absence of outflows in RBS 1124, but is beyond the scope of this work.

CONCLUSIONS

We have performed a detailed spectral analysis of new, broad-band (0.3–70 keV) X-ray data of the 'bare' AGN RBS 1124 obtained by *XMM*–*Newton* and *NuSTAR* in coordination. With the help of the broad coverage and high S/N data from *XMM*–*Newton* and *NuSTAR*, we are able to place robust constraints on various properties of the source.

(i) The spectral analysis reveals a moderately hard power-law continuum with $\Gamma \sim 1.8$ along with a soft excess below 2 keV, a weak neutral iron line, and curvature at high energies. The highdensity relativistic reflection model effectively explains the overall broad-band spectral continuum, while the iron line was attributed to a distant reflection.

(ii) Both variants of the high-density relativistic reflection models, *xillverCp* and *reflionx*, fit the data well. However they provide different spin constraints: $a^* > 0.835$ for Model 1 and $a^* > 0.236$ for Model 2. This discrepancy is driven by differences in the fine details of the calculations included in each model, which result in different reflection continuum fluxes at low energies (*<* 1 keV). In turn, this results in a different relative contribution to the overall flux of the soft excess from low-energy emission lines, and thus differing degrees of relativistic blurring required to produce a smooth soft excess.

(iii) These models require RBS 1124 to have a high disc density, log(n_e /cm⁻³) ≥ 19.2. Despite high density, RBS 1124 broadly adheres to the anticorrelation between $\log(n_e/cm^{-3})$ and $\log(m_{BH}m^2)$ expected for a radiation pressure dominated accretion disc. More than 90 per cent of the disc accretion power is inferred to be dissipated to the corona.

(iv) Our estimates of a low reflection fraction from the source $(R < 0.5)$ are consistent with the findings of Miniutti et al. (2010) and may suggest the presence of an outflowing corona.

(v) Despite a moderately high mass accretion rate, no detectable wind signatures are observed in the X-ray spectrum of RBS 1124. We speculate that this absence could be attributed to the face-on viewing angle of the source. Further studies of the source through optical spectroscopy could reveal additional insights into its outflows.

ACKNOWLEDGEMENTS

We thank the referee for their useful suggestions that helped us improve the clarity of the paper. JJ acknowledges support from the Leverhulme Trust, the Isaac Newton Trust and St Edmund's College, University of Cambridge. CR acknowledges support from Fondecyt Regular grant 1230345 and ANIDBASAL project FB210003. PK acknowledges the support provided by NASA through the NASA Hubble Fellowship grant HST-HF2-51534.001-A awarded by the Space Telescope Science Institute, which is operated by the Association of Universities for Research in Astronomy, Incorporated, under NASA contract NAS5-26555. This research has made use of data obtained with *NuSTAR*, a project led by Caltech, funded by NASA and managed by the NASA Jet Propulsion Laboratory (JPL), and has utilized the NUSTARDAS software package, jointly developed by the Space Science Data Centre (SSDC; Italy) and Caltech (USA). This research has also made use of data obtained with *XMM*–*Newton*, an ESA science mission with instruments and contributions directly funded by ESA Member States.

APPENDIX A : SOME EXTRA MATERIAL

Figs A1 and [A2](#page-12-0) show the MCMC analysis results for the parameter combinations from Model 1 and Model 2, respectively. The specifications of our MCMC sampling approach are outlined in Section [4.](#page-6-0) The uncertainty ranges for parameters derived from MCMC are consistent with those estimated by the ERROR command in XSPEC.

Figure A1. The corner plot shows the posterior probability distribution for the parameters from Model 1 obtained from the MCMC analysis using the GW algorithm. The contours in the figure enclose 68 per cent, 95 per cent, and 99.7 per cent of the probabilities.

Figure A2. The corner plot shows the posterior probability distribution for the parameters from Model 2 obtained from the MCMC analysis. The contours signify the same confidence intervals as quoted in Fig. [A1.](#page-11-0)
