1 INTRODUCTION

The determination of the masses (or equivalently mass-to-light ratios) of gas-poor galaxies has been an important issue since the discovery that galaxies are stellar systems like the Milky Way, with mass being a strong driver of many of their properties. Dynamical modelling methods of increased sophistication have been developed over the past decades, all based on the assumption that galaxies can be described as stationary systems. The first attempt at measuring dynamical masses of galaxies were based on the spherical virial equation (Poveda 1958; Spitzer 1969). These methods have the disadvantage that, for accurate results, they need to assume self-similarity in the galaxy light and mass distribution. More accurate methods allow for axisymmetry and take the galaxy light distribution into account. The first detailed axisymmetric models of real galaxies were based on the Jeans (1922) equations and assumed a distribution function that depends on two (out of three) integrals of motion (e.g. Binney et al. 1990; van der Marel et al. 1994; Emsellem et al. 1994b), but special classes of three-integral models were also used. Axisymmetric methods were developed to allow for a general orbital distribution, based on numerical orbital superposition method (e.g. Creton et al. 1999; van der Marel et al. 1998; Gebhardt et al. 2003; Thomas et al. 2004; Cappellari et al. 2006). Currently the most general available models assume galaxies can be approximated by a stationary triaxial shape (e.g. de Lorenzi et al. 2007; van den Bosch et al. 2008).

The above modelling techniques were developed under the assumption that gas-poor galaxies can be well described by stationary axisymmetric or triaxial spheroidal systems. However a key initial result of the ATLAS3d survey (Cappellari et al. 2011), hereafter Paper I is the fact that nearby gas-poor galaxies are actually dominated (86 per cent of them) by fast rotators (Krajnović et al. 2011; Emsellem et al. 2011, hereafter Paper II and Paper III), often with significant disk components and resembling spiral galaxies with the dust removed (Cappellari et al. 2011b). Paper VII, 30% of which at least are barred. The presence of these bars is a difficult problem for all modelling methods and therefore motivates the present study.

Bars are density waves which results in a tumbling potential: this figure rotation is often ignored in the popular dynamical modelling methods described above. Dynamical models of barred galaxies have been constructed in the past (e.g. Pfenniger 1984; Häfner et al. 2000; Zhao 1996). However, the existence of intrinsic degeneracies in the dynamical modelling of bars make the determination of mass quite uncertain even for such models. In fact even the full amount of information one can obtain today for external galaxies, namely the full line-of-sight velocity distribution (LOSVD) at every position on the sky, is not sufficient to uniquely constrain the two free parameters ($M/L$ and inclination) of a simple self-consistent axisymmetric model (Valluri et al. 2004; Krajnović et al. 2005; Cappellari et al. 2006; van den Bosch & van de Ven 2009). A barred model requires at least two extra parameters (the Position Angle (PA) and pattern speed of the bar) and dramatically increases...
the complexity of the orbital structure and the associated degeneracy of the problem, instead of improving the accuracy of the mass estimate: a broad range of parameters space may well fit the data equally well. Moreover, assuming a galaxy is barred also increases the degeneracy in the mass deprojection problem (e.g. Gerhard 1996), which is already mathematically non unique in the simple axisymmetric case (Rybicki 1987). The application of sophisticated barred models to large samples would be computationally challenging, but feasible exploiting the trivial parallelism of the problem. However, this brute-force approach does not remove the intrinsic degeneracies so it is not expected to increase the accuracy of the mass determinations, and for this reason does not seem justified.

An alternative approach consists of using some a priori information on the galaxy structure and make empirically-motivated restrictive assumptions on the models. This is the approach we are using in the systematic determination of the masses of the 260 early-type galaxies of the ATLAS$^{3D}$ survey (Cappellari et al. 2012). We are applying the Multi-Gaussian Expansion (MGE) technique (Emsellem et al. 1994a) to accurately describe the photometry of all galaxies in the survey (Scott et al. in prep) and use the Jeans Anisotropic MGE (JAM) modelling method (Cappellari 2008) to measure masses. The JAM method is based on a simple and very efficient solution of the Jeans equations which allows for orbital measure masses. The JAM method is that it was shown, using 25 real galaxies (Cappellari et al. 2006; Cappellari 2008), to agree well within the model uncertainties on the galaxy structure and make empirically-motivated restrictions on the models. This is the approach we are using in our investigation, and in Section 4 we compare the original and recovered values of the corresponding dynamical parameters.

The fitting of the MGE to the photometry follows the procedure applied by Scott et al. (2009) (see their Fig. 2) to deal with the presence of bars. This same approach is being applied to the MGE fits of the ATLAS$^{3D}$ sample (Scott et al. in preparation). The procedure allows to find the best fit to the photometry, maximising the

\[ \Sigma(x', y') = \sum_{k=1}^{N} \frac{L_k}{2\pi\sigma_k q_k} \exp \left( -\frac{1}{2\sigma_k^2} \left( x'^2 + y'^2 q_k^2 \right) \right) \]

where \( N \) is the number of adopted gaussian components, each having an integrated luminosity \( L_k \), an observed axial ratio \( 0 \leq q_k^2 \leq 1 \), a dispersion \( \sigma_k \) along the major axis, and a position angle (PA) \( \psi_k \) measured counter-clockwise from \( y' \) to the major-axis of the Gaussian, with \( (x', y') \) being the associated rotated coordinate system. Then, the deprojected MGE luminosity distribution in cylindrical coordinates can be expressed as:

\[ \nu(R, z) = \sum_{k=1}^{N} \frac{q_k}{(\sqrt{2\pi}q_k)^2} \frac{L_k}{\sqrt{2\pi}q_k} \exp \left( -\frac{1}{2\sigma_k^2} \left( R^2 + z^2 q_k^2 \right) \right) \]

where the \( k \)-th gaussian has the total luminosity \( L_k \), intrinsic axial ratio \( q_k \) and dispersion \( \sigma_k \). (In the present study \( \sigma_k = \sigma_k^2 \)). The intrinsic axial ratio \( q_k \) can then be written as:

\[ q_k^2 = \frac{q_k^2 - \cos^2 \theta}{\sin^2 \theta}, \quad \text{for } i \neq 0 \]

where \( i \) is the galaxy inclination.

2 MODELING AND N-BODY SIMULATIONS OF EARLY-TYPE BARRIED GALAXIES

2.1 Mass modeling

2.1.1 Multi-Gaussian Expansion method

We use in our study the Multi-Gaussian Expansion method described in Emsellem et al. (1994a) and Cappellari (2002). The technique basically consists of decomposing the luminosity into a number of concentric two-dimensional (2D) Gaussians. By fitting the detailed surface brightness distribution, the MGE formalism provides a description of the intrinsic luminosity density, which connects to the mass distribution via the assumed constant \( M/L \). From galaxy images this formalism allows us to generate realistic initial conditions for our N-body simulations using the method explained in Sec 2.3. The MGE parametrization is also the first and crucial step of the JAM modeling. Thus, a rigorous and robust approach is needed when producing the MGE model of a galaxy, as the predicted kinematics may significantly depend on the obtained mass distribution (see Sec 2.2). The method and software we adopt in our study to produce MGE parametrization is fully described in Cappellari (2002).

Once the best fit has been found, we have a description of the galaxy surface brightness distribution given as a sum of two-dimensional Gaussians which we can attempt to deproject. The deprojection of a galaxy surface brightness distribution is formally non-unique for all but edge-on cases, and the degeneracy can become severe at low inclinations (Rybicki 1987). The MGE method provides just one solution for the deprojection, in terms of a sum of three-dimensional Gaussians. This method has been intensively used and usually provides luminosity distributions consistent with observed photometry of existing galaxies, but the MGE method obviously does not remove the existing intrinsic degeneracy.

The deprojection of an MGE model can be done analytically once the viewing angles are known (see Monnet et al. 1992). When the system is assumed to be axisymmetric, only one viewing angle, the inclination \( i \) (\( i = 90^\circ \) for an edge-on system), is sufficient to retrieve the full three-dimensional luminosity distribution \( \nu \) (if the galaxy is not face-on).

In a coordinate system \( (x', y', z') \) centered on the galaxy nucleus with \( z' \) pointing toward us and \( (x', y') \) being the plane of the sky, the MGE surface brightness can be written as:

\[ \Sigma(x', y') = \sum_{k=1}^{N} \frac{L_k}{2\pi\sigma_k q_k} \exp \left( -\frac{1}{2\sigma_k^2} \left( x'^2 + y'^2 q_k^2 \right) \right) \]

2.1.2 MGE modeling of barred and unbanned S0 galaxies

The fitting of the MGE to the photometry follows the procedure applied by Scott et al. (2009) (see their Fig. 2) to deal with the presence of bars. This same approach is being applied to the MGE fits of the ATLAS$^{3D}$ sample (Scott et al. in preparation). The procedure allows to find the best fit to the photometry, maximizing the
minimum $q_k'$, and minimizing the maximum $q_k''$, while still being consistent with the projected galaxy image within the errors. For near face-on cases, a small deviation in the observed axis ratios implies an important change in the flatness (or roundness) of the mass distribution. As the previous procedure frequently ends with very similar lower and upper limits for $q_k'$, we force a common axis ratio for all Gaussians for such cases to keep an acceptable global shape for our MGE model.

When the bar clearly affects the projected photometry of our models (i.e., when it is easily detected), the method adopted for the MGE parametrization consists in forcing the lower and upper limit of the gaussian axis ratios. In this context, a bar can be considered as a perturbation of a disk structure. Bars, if fully fitted by MGE components, appear as Gaussians elongated along the apparent long axis of the bar. The presence of a bar tends to significantly affect the $q_k'$ values of a few Gaussians depending on its position angle, strength and length (the position angle of the bar PA$_{\text{bar}}$ being measured counter-clockwise from the projected major-axis of the galaxy). The resulting $q_k'$ could thus make the system look flatter (or rounder) than the corresponding axisymmetric case if the bar is seen end-on (resp. side-on). Previous tests made in Scott et al. (2009) showed that the best fitting MGE parametrization of a barred galaxy is usually not the one which allows the best fit to the observed kinematics (using JAM models). The kinematic fit is significantly improved when the Gaussians have constrained axial ratios such that the systems is forced to an axisymmetric "bar-less" MGE parametrization. As bars often only affect the photometry within a restricted radial range, we use the outer disk of each galaxy to constrain the imposed value of the Gaussian flattening. Figure 1 gives two examples of the resulting MGE fits for an axisymmetric simulation and a barred simulation, both including large-scale disks.

2.2 Jeans Anisotropic MGE Modeling

The JAM method is a powerful approach to model the stellar kinematics of early-type galaxies, providing a good description of the first two stellar velocity moments ($V$, $V_{\text{rms}}$) of a stellar system. This technique can be used to probe the dynamical structure of ETGs and does in principle allow the recovery of the inclination and the dynamical mass-to-light $M/L$ ratio. The JAM technique allows for a different $M/L$ and anisotropy for each individual MGE Gaussian component. However, the measurement of a global mass for real galaxies does not seem to require this extra generality, at least within 1$R_e$, where good quality integral-field data are available (e.g. Emsellem et al. 2004, and Paper I). For this reason the models we use make the following simple assumptions (a full description of JAM is provided in Cappellari 2008):

(i) An axisymmetric distribution of the mass.
(ii) A constant mass-to-light $M/L$ ratio.
(iii) A constant anisotropy described by the classic anisotropy parameter $\beta_z = 1 - (\sigma_z/\sigma_R)^2$ with $\beta_z \geq 0$.

When the mass distribution is represented via an MGE parametrization (see Sect. 2.1 above), the Jeans equations can be easily integrated along the line-of-sight as shown by Emsellem et al. (1994a) in the semi-isotropic case ($\sigma_z = \sigma_R \neq \sigma_\phi$) and by Cappellari (2008) in the anisotropic generalization ($\sigma_z \neq \sigma_R \neq \sigma_\phi$). Here we use the anisotropic formulas (equations 28 and 38 of Cappellari (2008)) to derive the projected first and second velocity moments ($V$ and $V_{\text{rms}}$) given a set of input parameters (MGE mass model, mass-to-light ratio $M/L$, anisotropy $\beta_z$), and thus find the best fitting values within a sampled predefined solution space (e.g., $\beta_z \geq 0$).

Such a JAM method has been systemically applied to SAURON integral-field stellar kinematics of all 260 early-type galaxies of the ATLAS$^{3D}$ sample. In the present study, we rely on mock ob-
The ATLAS^{SD} project - XII. M/L recovery of barred galaxies.

2.3 N-body simulations of regular-rotator galaxies

As the main motivation of our study is to find the influence of a bar on the recovery of basic dynamical parameters with the JAM method, we chose to use an N-body approach to generate simulations of barred early-type galaxies: knowing the exact input dynamics for these simulations, we can then compare the key parameters with those determined via the JAM modeling. We also made static realisations of a few (Hernquist and one typical axisymmetric lenticular) mass models, and thus only used the initial realisation of the N-body distribution. These models are detailed in Table 2 while details for evolved simulations are summarized in Table 1. The method to build the initial conditions for our simulations (to be evolved, or not) is detailed below.

2.3.1 Particle positions

Starting from the MGE parametrization of a mass distribution (after taking into account the mass-to-light ratio M/L), the initial positions of the particles can be computed easily. Each Gaussian represents a fraction of the total mass, so that given a total number of particles per component we can determine N_k, the number of particles of that k-th Gaussian. All components are truncated at a chosen radius. To set up the position of each particle, we use a standard realisation method with a random generator via the cumulative function of a (truncated) Gaussian function, scaling each spatial distribution with the corresponding spatial dispersion.

Table 1. Table providing a list of simulations with their labels and their specifications. Distances are set according to Paper I, N_p is the number of particles, \beta_{z_i} gives the anisotropy of the initial conditions as described in Section 2.3.2, \beta_{z_f} is the global anisotropy computed for the final state of our simulations, \sigma_{z_i}/\sigma_R gives the second relation for the geometry of the velocity dispersion ellipsoid for the initial conditions. The time given in the eighth column corresponds to the simulated time of evolution. The last column indicates whether a bar appeared or not in our simulations.

2.3.2 Dynamical structure

Given the particle position, we compute the velocity dispersion components \sigma_R, \sigma_\phi and \sigma_z solving Jeans Equations (Jeans 1922), within the MGE formalism of Elmegreen et al. (1994). For this work we use the anisotropic generalization of the method (equations 19–21 and 34 of Cappellari (2008)), which allows one to set arbitrary ratios \sigma_z/\sigma_R and \sigma_\phi/\sigma_R for the axes of the velocity ellipsoid, which is assumed to be cylindrically oriented. Values for these ratios can be set individually for each gaussian component, but in this study all Gaussians share the same geometry of its velocity dispersion ellipsoid. For some of the simulations initial conditions, we used the following (so-called \beta - \epsilon , with \epsilon the intrinsic galaxy ellipticity) relation to fix \sigma_{z_f}/\sigma_z:

\[
\beta_z = 1 - \left( \frac{\sigma_z}{\sigma_R} \right)^2 = 0.6 \times \epsilon
\]

This a purely empirical relation which seems to describe the general trend in the anisotropy of real fast rotator galaxies (Cappellari et al. 2007).

2.3.3 Simulation code

The numerical simulations are performed with a particle-mesh N-body code (Bournaud et al. 2007). The density is computed with a Cloud-in-Cell interpolation, and an FFT-based Poisson solver is used to compute the gravitational potential, with a spatial resolution and softening of 48 pc. Particle motions are integrated with a leapfrog algorithm and a time-step of 0.1 Myr. The number of particles and the time evolution of each model are given in Table 1.

3 INPUTS FOR JAM MODELS

3.1 Unbarred simulations

We first built four simple simulations based on the analytic Hernquist (1990) mass distribution

\[
\rho(r) = \frac{M a}{2 \pi r^2 (r + a)^3}
\]

...
where $M$ is the total mass and $a$ is a scale length. These simulations allowed us to quickly check the purely numerical accuracy of the JAM modeling method and of our starting-conditions generating software for spherical isotropic (Hern01), spherical anisotropic (Hern02), flat isotropic (Hern03) and flat anisotropic (Hern04) particle realisations. Flat Hernquist models are oblate systems derived from the Hernquist profile by forcing an axis ratio of 0.5 for the mass distribution. For all these simulations the inclination was recovered within an error of less than $2^\circ$ (besides the case of Hern01, for which the inclination is meaningless), the global anisotropy was accurately recovered within an error of $\pm 0.025$ and the error on $M/L$ never exceeded $1.5\%$.

We then considered a more realistic numerical test, using the MGE parametrization of the SDSS $r$-band image of the real galaxy NGC4754 and a constant anisotropy and we label this model $N4754ini$. When computing the particle velocities, we forced $\beta_z = 0.2$ for all Gaussians. In contrast to the above-mentioned Hernquist models, $N4754ini$ represents a complex multi-component object in terms of its mass distribution and kinematics, and is therefore expected to be more challenging for the JAM modeling method.

We also built two simulations, respectively based on the MGE parametrizations of NGC4570 and NGC4179, which were evolved via N-body simulations during 1.5Gyr (the face-on and edge-on projections of the final state are illustrated in [A1]). These two simulations can be considered as fully relaxed, and contrarily to $N4754ini$ and the Hernquist models, the resulting $\beta_z$ is measured not to be constant with radius. One important difference between $N4570axi$ and $N4179axi$ is that, while the initial conditions for $N4570axi$ were fixed as isotropic ($\beta_z = 0$), the ones for $N4179axi$ were those of a dynamically cold disk as described in Table I. No bar formed either for $N4179axi$ or $N4570axi$.

Projected velocity and velocity dispersion maps of our two axysymmetric simulations with variable $\beta_z$ are presented in Figure [A2]. The second velocity moment is dominated by the dispersion in the central region, and by the velocity in the outer parts. The profile of $V_{\text{rms}}$ also shows a central depletion.

Figure [A2] present the local anisotropy $\beta_z$ as measured in the meridional plane and the equatorial plane, computed on a cylindrical grid with linearly spaced cells in $R$, in $z$ and in angle $\phi$ where $(R,\phi,z)$ are the standard cylindrical coordinates, including a central cylindrical cell with a radius of $R_c = 0.01\, \text{kpc}$. This highlights the
fact the anisotropy is not constant in our axisymmetric simulations and that the central parts are more isotropic than the outer regions. In Figure 3 we show that the radial anisotropy profile (which is simply the azimuthal average of the equatorial computation) generally increases outwards for these axisymmetric simulations.

3.2 Barred simulations

We also developed bar simulations, $N4442bar$, and $N4754bar$, based on the initial MGE parametrizations of NGC4442 and NGC4754, respectively: these are the final state of two N-body simulations after 1.5 Gyr of evolution (face-on and edge-on projections of the final state can be found in [A]). To generate a bar, we force a cold dynamical structure in the initial particle realisations by setting in the initial conditions $\sigma_0 = \sigma_R/1.8$. The radial velocity dispersion $\sigma_R$ was set using the $\beta(z)$ function described in Eq. 4.

With these conditions, a bar appears in each of these simulations after only a few rotation period, namely between about 25 Myr and 50 Myr of simulated evolution. As mentioned, we let the galaxy evolve for 1.5 Gyr, to make sure that the bar is well settled.

$N4442bar$ presents the biggest bar (in size) of our simulations: we estimate a semi-major axis of 3.0 kpc. The size of the bar is determined using the radial flattening ($q_{\text{isophote}} = 1 - \epsilon_{\text{isophote}}$) and the position angle ($P_A_{\text{isophote}}$) of isophotes as done in Michel-Dansac & Wozniak (2006). Basically we define the end of the bar as the radius where isophotes are nearly round ($q_{\text{isophote}} > 0.9$) combined with an important change in the position angle. Using the same method we determine the semi-major axis of the bar for $N4754bar$ to be 2.2 kpc. Outside of the bar regions, our two simulations are characterized by a rotation pattern consistent with an axisymmetric disk-like system.

The velocity fields of our barred simulations are shown in the two lower panels of Figure 2. As for the axisymmetric cases, the $V_{\text{rms}}$ maps are dominated by velocity dispersion in the central parts and by the mean velocity in the outer parts. But in contrast to the $N4179axi$ and $N4754ini$ simulations, the barred simulations all show a peak in the center of the $V_{\text{rms}}$ maps. This apparent difference between the barred and unbarrred cases has important consequences, since this will condition the fit of the projected second velocity moment via a JAM model.

Figure 4 and Figure 5 show that the local anisotropy starts from a central value of 0.3, reaching a minimum of nearly 0.2 close to the end of the bar, then increasing in the outer parts of the model up to 0.7. The derivation of $\beta_z$ in the equatorial plane confirms the presence of a drop in $\beta_z$ in the outer parts of the bar.

3.3 Mock observations

As input for the JAM modeling, we simulated observations by projecting our simulations first with four different inclinations: $i = 25^\circ$; $i = 45^\circ$; $i = 60^\circ$ and $i = 87^\circ$. ($i = 0^\circ$ corresponding to the face-on projection, and $i = 90^\circ$ to the edge-on projection). The choice of a near edge-on projection instead of an exact edge-on projection was motivated by the goal of checking the accuracy of the inclination recovery. Indeed the edge-on projection does not allow an overestimation of $i$ and then limits the range of possible uncertainty. When a bar is present, we also used four different position angles for the bar, and this for each value of the inclination: $P_A_{\text{bar}} = 18^\circ$; $P_A_{\text{bar}} = 45^\circ$; $P_A_{\text{bar}} = 60^\circ$ and $P_A_{\text{bar}} = 87^\circ$. The position angle of the bar is measured counter-clockwise from the galaxy projected major-axis to the bar major-axis, so that $P_A_{\text{bar}} = 87^\circ$ is close to having the bar end-on and $P_A_{\text{bar}} = 18^\circ$ close to side-on. We also simulated the SAURON pixels size of $0.8$ assuming a distance for each model as given in Table 1 typical of ATLAS$^{3D}$ objects. Note that the $M/L$ provided in Table C1 could have been chosen as unity, considering that we will only probe here relative $M/L$. However, we favoured realistic values as to deal with sensible velocity measurements.

For real galaxies the photometry is available over a much larger field of view than the kinematics. For each projection, the MGE parametrization was achieved using a rather wide field of view of $401 \times 401$ pixels corresponding to $320.8$ arcsec, and including the full model. Then, the JAM modeling was fit on a $73 \times 73$ pixels map (58.4 arcsec) of the second velocity moment with the simulated galaxy centered on its nucleus, as this roughly corresponds to the setup for a single SAURON exposure.
4 RECOVERY OF PARAMETERS

The recovery of $i$, $\beta_z$ and $M/L$ with JAM is done on $V_{\text{rms}}$ maps only. The prediction of $V$ and $\sigma$ require an extra assumption on the constancy of the tangential anisotropy of the JAM models. This assumption may not be well verified in the simulations, especially in barred ones. However, the accuracy in the determination of the above parameters only depends on the ability of JAM to reproduce the $V_{\text{rms}}$, and not the $V$ and $\sigma$ fields separately. Details of the method to calculate $V$ and $\sigma$ can be found in Cappellari (2008).

4.1 Recovery of $\beta_z$ and inclination

As shown in Figure 3, the anisotropy varies significantly when going from the inner to the outer parts of our simulations.

The JAM modelling method allows for a different anisotropy $\beta_z$ for every individual MGE Gaussian. Here we limit ourselves to the simple case where $\beta_z$ is constant for the whole model. Tests using 25 real galaxies (Cappellari et al. 2006; Cappellari 2008) have shown that even with constant anisotropy the recovered $M/L$ agrees with the one derived with Schwarzschild models, which allow for a general anisotropy distribution. The extra generality of JAM is therefore not required in this case. Thus, for comparison, we compute a global anisotropy for our simulations by doing a luminosity-weighted average of the local anisotropy for all of our simulations. In the following we discuss the issue of the inclination-anisotropy degeneracy intrinsic to galaxy dynamics and also the important influence of the MGE parametrization on the recovery of the global anisotropy. The global anisotropy recovered with the JAM modeling method is noted $\beta^\text{JAM}_z$ and the one computed directly from the simulation $\beta^\text{SIM}_z$.

4.1.1 Anisotropy-inclination degeneracy

As shown in Krajnovi´ c et al. (2005) and with more galaxies in Cappellari et al. (2006) there is an intrinsic degeneracy in the dynamical problem between the recovery of the inclination and the anisotropy: given the observed photometry, the observed kinematics can be reproduced in detail for a wide range of inclinations, by varying the orbital make up of the models. This degeneracy persists even in the restricted case in which the anisotropy is assumed to be constant for the whole galaxy Cappellari (2008). The degeneracy can only be broken by making empirically-motivated assumptions on the anisotropy. This was the approach adopted by Cappellari (2008), who showed using a small sample of galaxies that, if $\beta_z$ is assumed to be positive, as determined using general models on large samples of galaxies (Cappellari et al. 2002; Thomas et al. 2009), the correct inclination can be recovered from the observed integral-field kinematics.

Here we test the inclination recovery via JAM using N-body simulations of both unbarred (i.e. N 4179axi and N 4570axi) and in particular barred galaxies (i.e. N 4442bar and N 4754bar), for which the inclination is known. We confirm the fact that, despite the inclination-anisotropy degeneracy the inclination can be recovered in axisymmetric simulations, and we additionally find that the inclination can be recovered even in barred simulations. The influence of $i$ on the second velocity moment map is important at low inclination. A slight change in the inclination implies a significant change in $V_{\text{rms}}$ (which is more directly related to the change in the axis ratio), and then allows a good recovery of the inclination value $i$. At higher inclination, the change in ellipticity is milder and $V_{\text{rms}}$ is less influenced by small variations. In all cases, the uncertainty never exceeds a few degrees, even when the fit can be considered difficult due to the presence of non-axisymmetric features such as a bar.

We also confirm that at low inclinations ($i \lesssim 40^\circ$) there is a degeneracy in anisotropy in the $V_{\text{rms}}$ fit, essentially preventing any
The ATLAS$^{3D}$ project - XII. $M/L$ recovery of barred galaxies.

4.1 Influence of the mass deprojection

While the inclination-anisotropy degeneracy is intrinsic to the galaxy dynamics and determines the uncertainties for the recovered global anisotropy and the inclination, $\beta^\text{MGE}$ is also influenced by the mass deprojection. For regular axisymmetric simulations such as $N4179axi$ and $N4570axi$, the MGE parametrization is relatively robust, and $\beta^\text{MGE}$ is generally very close to the known intrinsic value $\beta_i$ (see Figure 6). The deviations near face-on view are due to the degeneracy in the mass deprojection at that low inclination.

For the barred simulations $N4442bar$ and $N4754bar$, the presence of the bar implies that axisymmetric models cannot reproduce the true stellar density distribution. This means that our MGE parametrization can only provide an approximation. Fig. [7] and Fig. [8] illustrate the impact of the degeneracy in the mass deprojection of barred galaxies. The deprojected surface brightness of a barred galaxy is shown for three inclination of the galaxy ($i = 25^\circ$, $i = 60^\circ$ and $i = 87^\circ$) and two positions of the bar ($PA_{\text{bar}} = 18^\circ$ and $PA_{\text{bar}} = 87^\circ$). Close to edge-on ($i = 87^\circ$, bottom panels), the reconstructed deprojected models do a reasonable job at fitting the true edge-on surface brightness contours. When the bar is close to end-on, the impact of assuming an axisymmetric model becomes more visible. At the other extreme end, near face-on models ($i = 25^\circ$, top panels) have deprojected contours which significantly depart from the true edge-on ones. This is mostly due to the fact that a small change in the fitted axis ratio of the Gaussians has a large impact on the intrinsic axis ratio after deprojection: this is further illustrated and emphasized in Appendix [B]. For intermediate viewing angles ($i = 60^\circ$, middle panels), the deprojected photometry fits reasonably well the true edge-on contours, while again, the discrepancy is emphasised in the region of the bar when it is initially viewed edge-on. For a real, observed near face-on galaxy, it is hard to know how close the MGE fitting process would get from the intrinsic axis ratio of the outer disk, as it would depend on e.g., the regularity of the disk (for example, its lopsidedness), the signal to noise and contamination from the sky. As shown in Figure 5, changes induced by the anisotropy of area $A$ is increased ($\beta^\text{MGE}$ and isotropic $\beta_i$) or end-on ($PA_{\text{bar}} = 18^\circ$) and isotropic $\beta_i$) is also influenced by the ellipticity $\epsilon$ and projected edge-on. The first one (named Test01) is based on a MGE parametrization with constant $\epsilon = 1 - q$ and isotropic kinematics (black solid line on the Figure 10). The second one (Test02) is also isotropic but with a non constant ellipticity in the mass distribution, $\epsilon$ increasing with radii (black dashed line).

These two test models highlight the fact that when the considered area $A$ is increased ($V/\sigma$) increases as to roughly follow the constant anisotropy lines. The axisymmetric model $N4179axi$ also lay on a constant anisotropy line although its dynamical structure presents a $\beta$ gradient. Barred simulations present a different behavior depending on $PA_{\text{bar}}$. With broad field of view (FOV) the only effect of the bar is seen through ($V/\sigma$) which decreases when...
Figure 7. Effect of the inclination on the deprojection of MGE models for $i = 25^\circ$, $i = 60^\circ$ and $i = 87^\circ$. In the first and second columns the MGE fitting (red lines) of the projected mass distribution (black contours) is shown for $P_{\text{bar}} = 18^\circ$ and $P_{\text{bar}} = 87^\circ$. The edge-on deprojections of the two latter MGE fitting are represented in the third and fourth columns respectively, superposed to the azimuthally averaged projected density.

PA$_{\text{bar}}$ increases. But when the size of the FOV is of the order of the bar size, $\epsilon$ is affected by PA$_{\text{bar}}$ and then the projections spread over a wide range of anisotropy. The intrinsic ellipticity of the MGE parametrization plays here an important role for the anisotropy recovery.

We made a second test to better understand the effect of the MGE parametrization on a model of barred object. From the same projection we created two different MGE models: the first one is a “free” model with gaussian axis ratios left unconstrained; for the second one we forced the maximum and the minimum axis ratio as we do know the intrinsic mass distribution. We did not include here the case $P_{\text{bar}} = 45^\circ$ for which the MGE parametrization is forced to be neither flatter nor rounder than the axisymmetric case. As expected, when we forced the axis ratio during the MGE parametrization, the global anisotropy $\beta_J^z$ recovered was found to be much closer to $\beta_{\text{SIM}}^z$ as shown in Figure 11. We can then assume that the accuracy in the recovery of the global anisotropy is mainly biased by the MGE parametrization of the photometry.

Unfortunately, we cannot always objectively choose the best deprojected model when we apply the JAM modeling method to real observations. And for barred galaxies the accuracy on $\beta_z$ will only be improved if we can really see the bar or have strong evidence for its presence.

4.2 Recovery of $M/L$

The Mass-to-Light ratio $M/L$ is the third parameter (after the inclination $i$ and the global anisotropy $\beta_z$) computed with the JAM modeling method.

When using the initial conditions, we simply compare the recovered $M/L$ with the input ones. For evolved galaxies we used instead, as our reference, the $M/L$ computed from the direct application of the virial relation $2K + W = 0$ to the simulation particles, where $K$ is the total kinetic energy and $W$ is the total potential energy of our simulations. The relation makes no other assumption that a steady state, and thus provides the natural benchmark against which to compare stationary dynamical models. In general one expects simulations and real galaxies to satisfy the relation quite accurately, so that the virial $M/L_{\text{vir}}$ will agree with the input one $M/L_{\text{SIM}}$ and no distinction needs to be made. However Thomas et al. (2007) found that $M/L_{\text{vir}}$ can differ from the input one at the 5% level, due to non stationarity, and our results agree with theirs. As we are not interested on investigating the stationarity of the model, but only the biases of the modelling method, for
The ATLAS$^3$D project - XII. M/L recovery of barred galaxies.

Figure 8. Same as Figure 7 with a field of view of $5\text{kpc} \times 5\text{kpc}$.

Figure 9. Recovered value of the global anisotropy for barred simulations as a function of the projection inclination for $N4442_{\text{bar}}$ (left) and $N4754_{\text{bar}}$ (right) for different $\text{PA}_{\text{bar}}$. The horizontal black solid line represent the value of $\beta_{\text{SIM}}^{2\text{DM}}$ and the vertical lines shows the inclinations of projection.
Figure 10. Positions of edge-on projections of all models in the \((V/\sigma, \epsilon)\) diagram. The two tests models described in Section 4.1.2 are in black. The green line and the thin black solid lines correspond to isotropy and constant anisotropy in the diagram with a step of 0.1 from left to right. The cyan line corresponds to \(N4179axi\); the yellow one to \(N4570axi\); the blue ones to \(N4754bar\) and the red ones to \(N4442bar\). For barred simulations the solid line refers to \(PA_{bar} = 18^\circ\); the dashed one to \(PA_{bar} = 45^\circ\) and the dash-dotted one to \(PA_{bar} = 87^\circ\) (we removed the case \(PA_{bar} = 60^\circ\) for better legibility). The wider FOV is represented by a square and our reference FOV in the present study by a triangle.

Figure 11. Recovered values of the global anisotropy as a function of the projection inclination for two different MGE parametrization of the same model. The color solid lines are the values recovered with a model with forced axis ratio for the MGE parametrization and the dash-dot lines are for a free MGE parametrization (see Section 4.1.2). Note that the blue solid line and the blue dash-dot line are overlapping. The horizontal black line is the value \(\beta_{z}^{SIM}\) computed from the model.

Figure 12. Recovered value of \(M/L\) for non barred simulations \(N4179axi\) and \(N4570axi\) as a function of the inclination of projection. In these regular axisymmetric simulations we find an error of 1.5\% on \(M/L\) (excluding the near face-on projection).

Figure 13. Recovered value of \(M/L\) for \(N4754bar\) as a function of the projection inclination for different values of \(PA_{bar}\).

maximum accuracy we use as reference \(M/L_{vir}\) in all the comparisons which follow.

To probe the robustness of our method we applied it to the four Hernquist particle realisations created from the analytic formula of Hernquist (1990). The results both in the recovery of the global anisotropy and the \(M/L\) were excellent, with an accurate recovery of \(\beta_{z}\) and errors on \(M/L\) of less than 1.5\%. Whilst these simulations are basic and do not reproduce the complexity of a real galaxy, this is a reassuring test of our machinery.

An intermediate case between simple analytic simulations and real galaxies, is the \(N4754ini\) model which is just a regular axisymmetric rotating galaxy with a constant anisotropy. Its mass distribution corresponds to a real galaxy but its intrinsic dynamics are simple, as the velocity anisotropy is set to be constant throughout the galaxy. The global anisotropy is well recovered within 0.025 and the mass-to-light ratio is recovered with an error of less than 1.5\%. Although unrealistic, this case helps isolate the influence of a variable anisotropy on the results of the JAM modeling method.

We then used the JAM modeling method on \(N4179axi\) and \(N4570axi\) to explore any systematic bias that may be present with-
out the presence of a bar. Results are shown in Figure 12 and JAM fitting in Fig. D1 and Fig. D2. Figure 12 emphasizes that one can expect significant overestimations of $M/L$ up to $\sim 10\%$, when the galaxy is close to face-on. This important fact is illustrated with an analytic test in Fig. 4 of Cappellari et al. (2006) and with the galaxy NGC0524 in Fig. A1 there. Here we confirm it with the present simulations. In what follows we will focus on the higher inclinations. However, one should keep in mind that the $M/L$ of nearly face-on galaxies has to be treated with caution. For $i = 45^\circ$; $i = 60^\circ$ and $i = 87^\circ$ then, we find that in regular axisymmetric cases $M/L$ is recovered with a negligible median bias, and a maximum error of just 1.5%.

Figure 13 and Figure 14 respectively present the results of JAM modeling of N4754bar and N4442bar. As for axisymmetric cases, we only consider here inclination projections with $i \geq 45^\circ$. For high inclination projections the $M/L$ is recovered within 3% for a $PA_{\text{bar}} = 45^\circ$, which represents the average for random orientations. However the bias in the recovery can reach up to 15% in our tests cases. But the main point is that the recovered $M/L$ is correlated with the position angle of the bar, $PA_{\text{bar}}$. The more the bar is seen end-on, the larger the overestimation, due to the larger velocities of the stars moving along the bar, and towards the line-of-sight, with respect to the other directions in the disk plane. The reason is that the presence of a bar produces a peak in the $V_{\text{rms}}$ maps which is not present in the purely axisymmetric case (see Figure 2). In order to fit this peak, the JAM model tend to larger $M/L$ values. Moreover, the amplitude of the peak increases with $PA_{\text{bar}}$, which explains why the value of $M/L_{\text{JAM}}$ also increases with the position angle of the bar. The exclusion of the central regions helps to reduce the bias introduced by the bar in $M/L_{\text{JAM}}$, but in cases where the bar dominates the whole field of view, we cannot expect to get rid of its influence.

The case when the bar is seen side-on ($PA_{\text{bar}} = 18^\circ$) for $i = 45^\circ$; $i = 60^\circ$ and $i = 87^\circ$ is a special configuration for the mass deprojection. As the flat bar is deprojected as a flattened disk (see Fig 3), following the axisymmetric assumption, the JAM model is unable to reproduce the global shape of the $V_{\text{rms}}$ map (see Fig 12 D10 right left panel). The error on the recovered mass-to-light ratio can be up to $\sim 10\%$. In fact the global shape of the $V_{\text{rms}}$ map is dictated by the global anisotropy. The mass-to-light ratio essentially adjusts the fit to the global level of the second velocity moment.

The position of the bar $PA_{\text{bar}} = 45^\circ$ is a useful reference, as it represents the average value for random orientations. As previously mentioned in this case the MGE parametrization is hardly affected by $PA_{\text{bar}}$. In this configuration the error on $M/L$ does not exceed 3%, although the $V_{\text{rms}}$ map is not reproduced. Basically for projections with $PA_{\text{bar}} < 45^\circ$ $M/L$ is expected to be underestimated while for projections with $PA_{\text{bar}} > 45^\circ$ it is overestimated.

Then for $PA_{\text{bar}} = 60^\circ$ and $PA_{\text{bar}} = 87^\circ$, the bar produces a vertically elongated structure in projection and an artificially round bulge when deprojected as an axisymmetric system. However the reproduction of the $V_{\text{rms}}$ shape is still a hard task for the JAM model (see Fig 12 D9, D6 Fig D4 right column). A brief investigation pertaining to the influence of the MGE parametrization on $M/L_{\text{JAM}}$, illustrated by Figure 15 shows that forcing the flattening of the mass distribution in the JAM model does not really affect $M/L_{\text{JAM}}$, except for $PA_{\text{bar}} = 87^\circ$. For this bar position the accuracy in $M/L_{\text{JAM}}$ is increased, but at the same time, as previously mentioned in Section 4.1, the accuracy on the recovered global anisotropy is decreased. The prediction of the $V$ and $\sigma$ fields, are however significantly improved, when forcing $q_{b1}$, as is already shown in figure 3 of Scott et al. (2009).

To sum up, when a bar is present the $M/L$ overestimation or underestimation with the JAM modelling method are clearly due: (i) to the fact that the mass is incorrectly deprojected as too flat or too round, when the bar is edge-on or side-on respectively ; and (ii) to the fact that the projected second moments are lower or higher when the bar is edge-on or side-on respectively.

To reduce the effect of the bar, one possible solution is to fit the JAM model only to regions where the bar has little or no influence. We therefore investigated the effect of the size of the field of view (FOV) on $M/L_{\text{JAM}}$. One could expect that when increasing the FOV further we could minimize the effect of the bar on the fit and thus reach a better accuracy in the recovering operation. To test this, we increased the FOV of our mock data and repeated the JAM fitting procedure (the MGE parametrization was not affected as it is anyway done on a projection of the simulations with a very large field of view). Figure 16 illustrates $M/L_{\text{JAM}}$ as a function of the size of one side of the FOV normalized by the size of the bar for N4754bar. We find that, as expected, the FOV plays a role in the recovered values. When the size of the FOV exceeds the bar

\begin{figure}

\centering
\includegraphics[width=\textwidth]{figure15.png}
\caption{Recovered value of the mass-to-light ratio as a function of the projection inclination. The color solid lines are the values recovered with a model with forced axis ratio for the MGE parametrization and the dash-dot lines are for a free MGE parametrization.}
\end{figure}
size $\Delta M/L$ decreases and seems to tend to a limit value. This is expected as we cannot totally get rid of the effect of the bar in the $V_{\text{max}}$ maps. In our study, the typical fitted field of view is quite comparable to the size of the bar itself, meaning that our previous results are close to the worst case scenario. The relative size of the bar with respect to the size of the field of view is an important ingredient for the recovery of the mass-to-light ratio.

To conclude, when modeling a barred galaxy assuming an axisymmetric mass distribution, the $M/L$ is on average (at $PA_{\text{bar}} = 45^\circ$) still well recovered. It can, however, be overestimated, when the bar is parallel to the line-of-sight, or underestimated, when the bar is orthogonal to the line-of-sight, by up to 15% (in our tests). The amplitude of these errors mainly depend on the position angle of the bar $PA_{\text{bar}}$, but also on the size of the FOV. Excluding the most central parts and increasing the FOV would naturally tend to reduce the influence of the bar without removing the error on $M/L$ entirely.

5 CONCLUSION

This paper focuses on the study of the possible biases in the $M/L$ and anisotropy determination for barred simulations, when using axisymmetric dynamical models. This extends previous studies (Thomas et al. 2007) of triaxial and prolate merger remnants to axisymmetric and barred simulated disk galaxies that better resemble observed fast early-type rotators which constitute the large majority of the gas-poor population in the nearby Universe (see Paper II and Paper III). We do this by generating N-body simulations of objects with properties similar to observed galaxies, both with and without bars. These are projected at various viewing angles and used to generate mock observations that closely resemble real data. These data are then fed into the JAM modeling machinery as for real data, the difference being that the intrinsic values of the free JAM model parameters ($i, \beta_z, M/L$) are known for the simulated data set.

The errors in the recovered inclination increase with inclination due to the fact that, as previously noticed, the models predictions are sensitive to the intrinsic axial ratio of the MGE models. This implies that for nearly face-on inclinations, where the intrinsic axial ratio of the models change rapidly, the inclination is formally constrained to a fraction of a degree. This formal accuracy is, however, compensated by a broader degeneracy in the mass deprojection, leading to a small negative bias in the inclination. In practice, for the four simulations we constructed (40 different projections in total), the errors never exceeded $5^\circ$.

We confirm previous results that the $M/L$ can be recovered within a few percent when the simulated galaxies are nearly axisymmetric, except for nearly face-on view ($i \lesssim 30^\circ$), for which the $M/L$ can be significantly overestimated. The global anisotropy $\beta_z$ can be difficult to recover, especially at low inclination (near face-on) due to the inclination-anisotropy degeneracy. This degeneracy implies a significant uncertainty on $\beta_z$ at low inclination, but a smaller error at high inclination. The global anisotropy is primarily influenced by the flattening (or the roundness) of the MGE parametrization of the projected luminosity. In the case of regular axisymmetric objects, the main issue is the intrinsic mathematical degeneracy of the luminosity deprojection at low inclination, which affects any axisymmetric deprojection method, including the adopted MGE one. This results in small deviations of the recovered global anisotropy from the value computed from the numerical simulations; $\beta_z$ is well recovered.

When a bar is present, the mass deprojection becomes the main uncertainty in the models. The deprojected axisymmetric model will be naturally different from the true non-axisymmetric barred distribution and will change as a function of the observed PA. Consequently the predicted $V_{\text{max}}$ of the models, as well as the corresponding best fitting $\beta_z$ will change as a function of the PA and can be quite different from the true axially-averaged value.

The mass-to-light ratio is less sensitive to the MGE parametrization than the global anisotropy, but it is biased due to the intrinsic dynamics of the system we want to model. We find that $M/L$ is mainly influenced by the position of the bar and the size of the field of view. The error depends upon the position angle of the bar $PA_{\text{bar}}$ and can be up to 15%. Including only regions far from the bar allows a reduction of the error, but cannot generally avoid it completely.

Our study provides an estimate of the $M/L$ error that can affect the determination of dynamical $M/L$ via axisymmetric models, and in particular using the JAM method. The large variety of possible shapes, sizes and orientations of bars in galaxies, each with specific dynamics, prevents us from quantifying the exact errors made for individual galaxies. One should also keep in mind that our study is done on simulations of relatively weak bars. Therefore, the error on the estimated $M/L$ when modelling galaxies exhibiting stronger bars is expected to be larger. The objects studied here are still representative ATLAS$^3D$ fast rotators, this study therefore providing clear guidelines when applying axisymmetric modelling to such large samples.

APPENDIX B: MGE DEPROJECTION

We illustrate with the following figure the intrinsic degeneracy present in the deprojection of inclined galaxies.

APPENDIX C: JAM RECOVERY SUMMARY

APPENDIX D: JAM FITTING
Figure A1. Face-on (left panels) and edge-on (right panels) projections of the final state of the four simulations. From top to bottom: $N_{4179\text{axi}}$, $N_{4570\text{axi}}$, $N_{4442\text{bar}}$ and $N_{4754\text{bar}}$. 
Figure A2. Same as Fig A1 with a field of view of 10kpc × 10kpc.
Figure B1. Degeneracy in the edge-on deprojected luminosity with a field of view of $15\, \text{kpc} \times 15\, \text{kpc}$ (left column) and $5\, \text{kpc} \times 5\, \text{kpc}$ (right column). The first three rows represent the edge-on deprojection of MGE models with an apparent axis ratio $q' = 0.907$, $q' = 0.910$ and $q' = 0.920$ (from top to bottom respectively) when $i = 25^\circ$, superposed to the edge-on averaged projected luminosity of $N4754\, \text{bar}$ (black contours). In the last row the projected luminosity with $i = 25^\circ$ is plotted for all the three previous MGE models in addition to the luminosity contours of $N4754\, \text{bar}$ with $i = 25^\circ$ and $P/A_ker = 87^\circ$. We see that in this latter case, even though the projected models are indistinguishable, the deprojected ones can be very different. This is a manifestation of the unavoidable intrinsic degeneracy in the mass deprojection of axisymmetric bodies at low inclination.

</table>

Table C1. Table summarizing the values of $i$, PA$_{\text{bar}}$, $\beta_z$ and M/L of our mock observations and the values recovered by the JAM modelling method.
Figure D1. Comparison between the simulations projected velocity maps and the best JAM fitting for N4179 at the four angles of projection.
Figure D2. Comparison between the simulations projected velocity maps and the best JAM fitting for N4570axi for the four angles of projection.
Figure D3. Comparison between the simulations projected velocity maps and the best JAM fitting for N4442bar for $i = 25^\circ$ and the four PA$_{\text{bar}}$. 
Figure D4. Comparison between the simulations projected velocity maps and the best JAM fitting for $N4442_{\text{bar}}$ for $i = 45^\circ$ and the four $\text{PA}_{\text{bar}}$. 
Figure D5. Comparison between the simulations projected velocity maps and the best JAM fitting for N4442bar for $i = 60^\circ$ and the four PA_{bar}.
Figure D6. Comparison between the simulations projected velocity maps and the best JAM fitting for N4442bar for $i = 87^\circ$ and the four PA$_{\text{bar}}$. 
Figure D7. Comparison between the simulations projected velocity maps and the best JAM fitting for $N4754bar$ for $i = 25^\circ$ and the four PA$_{bar}$. 
Figure D8. Comparison between the simulations projected velocity maps and the best JAM fitting for N4754bar for $i = 45^\circ$ and the four PA$_{bar}$. 
Figure D9. Comparison between the simulations projected velocity maps and the best JAM fitting for $N^{4754}_{\text{bar}}$ for $i = 60^\circ$ and the four PA$^{\text{bar}}$.
